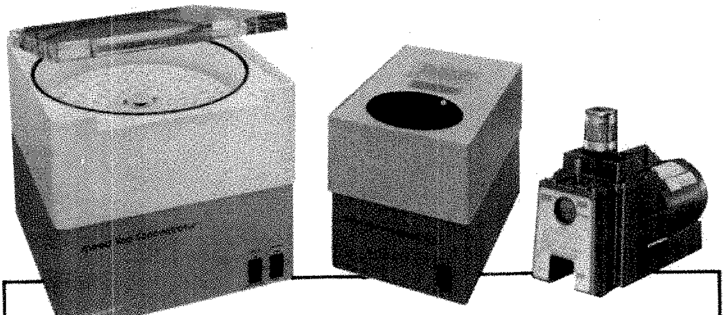
MULTI-SAMPLE/LARGE VOLUME

200 VIAL SPEED VAC®
EVAPORATOR/CONCENTRATOR

FOR RESEARCH AND CLINICAL LAB

- Virtually 100% solids recovery
- No bumping or foaming losses
- Handles oversize containers
- Special microplate rotor



SVC200H Speed Vac® Concentrator for hormones, anti-depressants, acetaminophen, prostaglandins, antibodies, concentration and harvesting

Applies both vacuum and centrifugal force to hold solids while evaporating solvent. Proven over years of reliable service. Complete line of accessories includes vacuum, traps to −90°C, heating, switchover-to-vacuum pump system, and extensive rotor library including our special 8-Microplate Rotor. THE MUSCLE SPINDLE

Edited by I A Boyd and M H Gladden

Muscle spindles are modified muscle fibres with both sensory and motor functions that have a key role in both dynamic and static muscle function. Research suggests that the muscle spindle is far more complex in terms of structure and function than was previously thought. This book, based on an international meeting attended by the world's foremost authorities, provides an up-to-date account of the main features of spindle structure and physiology in mammals.

☐ Edited proceedings of the first full international meeting on muscle spindle.
☐ Includes new research which shows this to be an area of great importance to neurophsysiologists.
☐ Edited by two acknowledged experts on the subject.
☐ Will be of interest to all neurophysiologists, pharmacologists and physiologists.

CONTENTS

The Contributors Preface PART 1: Morphology of Mammalian Muscle Spindles (Chapters 1–17) Review – I A Boyd and M H Gladden PART 2: Internal Working of Muscle Spindles (Chapters 18–35) Review – I A Boyd and U Proske PART 3: Static and Dynamic Fusimotor Neurones and their Reflex Control (Chapters 36–47) Review – M H Gladden and P R Murphy PART 4: Novel Experimental and Analytical Methods Used to Examine Behaviour of the Muscle Spindle (Chapters 48–57) Review – I A Boyd and J R Rosenberg

GUIDE TO AUTHORS

Authors should be aware of the diversity of *Nature*'s readership and should strive to be as widely understood as possible.

Review articles should be accessible to the whole readership. Most are commissioned, but unsolicited reviews are welcome (in which case prior consultation with the office is desirable).

Scientific articles are research reports whose conclusions are of general interest or which represent substantial advances of understanding. The text should not exceed 3,000 words and six displayed items (figures plus tables). The article should include an italic heading of about 50 words.

Letters to *Nature* are ordinarily 1,000 words long with no more than four displayed items. The first paragraph (not exceeding 150 words) should say what the letter is about, why the study it reports was undertaken and what the conclusions are.

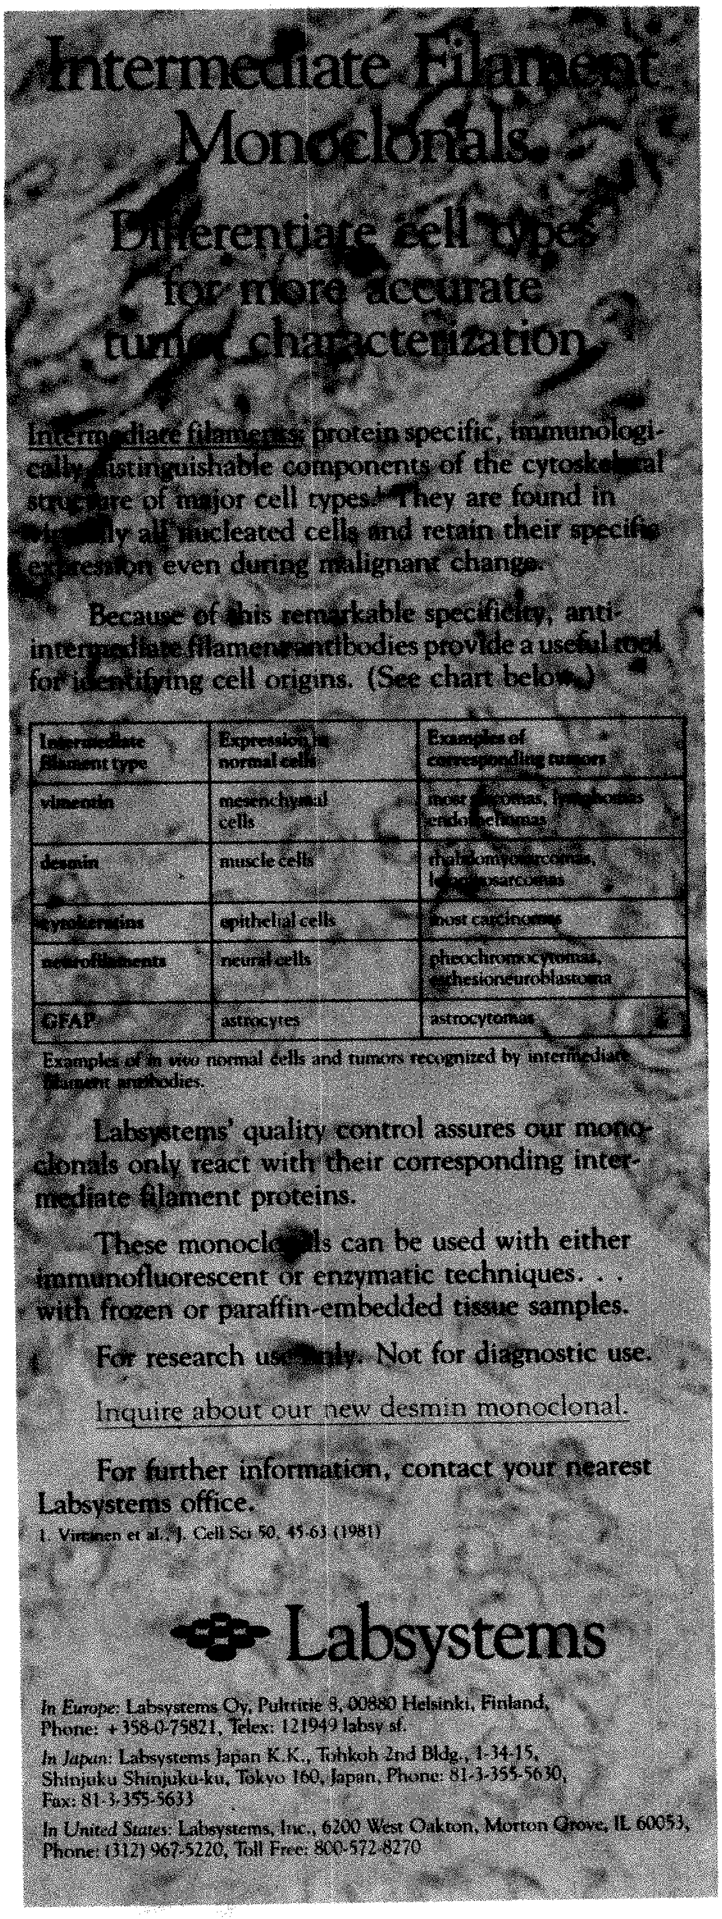
Matters arising are brief comments (up to 500 words) on articles and letters recently published in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted.

Manuscripts may be submitted either to London or Washington). Manuscripts should be typed (double spacing) on one side of the paper only. Four copies are required, each accompanied by copies of lettered artwork. No title should exceed 80 characters in length. Reference lists, figure legends, etc, should be on seperate sheets, all of which should be numbered. Abbreviations, symbols, units, etc, should be identified on one copy of the manuscript at their first appearance.

References should appear sequentially indicated by superscripts, in the text and should be abbreviated according to the *World List of Scientific Periodicals*, fourth edition (Butterworth 1963-65). The first and last page numbers of each reference should be cited. Reference to books should clearly indicate the publisher and the date and place of publication. Unpublished articles should not be formally referred to unless accepted or submitted for publication, but may be mentioned in the text.

Each piece of artwork should be clearly marked with the author's name and the figure number. Original artwork should be unlettered. Suggestions for cover illustrations are welcome. Original artwork (and one copy of the manuscript) will be returned when manuscripts cannot be published.

Requests for permission to reproduce material from Nature *should be accompanied by a self-addressed (and, in the case of the United Kingdom and United States, stamped) envelope.*



Intermediate Filament Monoclonals.

Differentiate cell types for more accurate tumor characterization.

Intermediate filaments: protein specific, immunologically distinguishable components of the cytoskeletal structure of major cell types.[1] They are found in virtually all nucleated cells and retain their specific expression even during malignant change.

Because of this remarkable specificity, anti-intermediate filament antibodies provide a useful tool for identifying cell origins. (See chart below.)

Intermediate filament type	Expression in normal cells	Examples of corresponding tumors
vimentin	mesenchymal cells	most sarcomas, lymphomas endotheliomas
desmin	muscle cells	rhabdomyosarcomas, leiomyosarcomas
cytokeratins	epithelial cells	most carcinomas
neurofilaments	neural cells	pheochromocytomas, esthesioneuroblastoma
GFAP	astrocytes	astrocytomas

Examples of *in vivo* normal cells and tumors recognized by intermediate filament antibodies.

Labsystems' quality control assures our monoclonals only react with their corresponding intermediate filament proteins.

These monoclonals can be used with either immunofluorescent or enzymatic techniques. . . with frozen or paraffin-embedded tissue samples.

For research use only. Not for diagnostic use.

Inquire about our new desmin monoclonal.

For further information, contact your nearest Labsystems office.

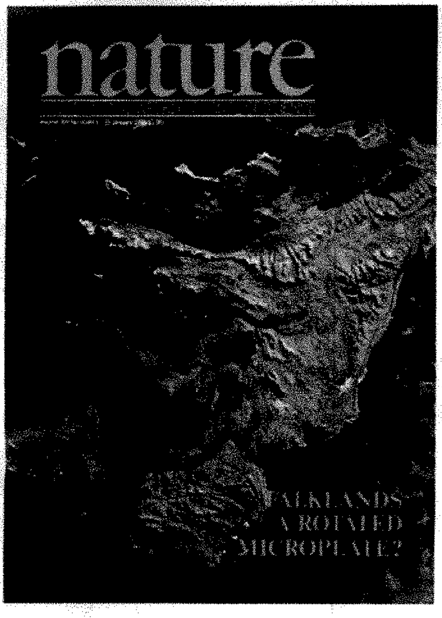
nature

NATURE VOL. 319 9 JANUARY 1986



Palaeomagnetic evidence suggests that the Falkland Islands underwent a rotation of approximately 120° during the early stages of the break-up of Gondwanaland, and that they were originally adjacent to the Transkei area of South Africa. The islands probably first moved as a microplate while Antarctica was separating from southern Africa, and drifted to their present position, undergoing further rotation, during the opening of the South Atlantic. See p.131.

FOR RESEA
R&D
(800) 3
TGF-BETA
M.W. stds.

TGF-beta is an extremely stable, multi-functional growth factor, active in picomolar quantities. The effect of the molecule is largely governed by the cell line under investigation.

Some of the more notable reported effects are:[1]

- Reversibly confers the transformed phenotype
- Provides synergistism with EGF and/or TGF-alpha
- Inhibits growth of certain carcinoma cell lines
- Inhibits terminal differentiation of pre-adipocytes
- Promotes *in vivo* wound healing
- Mimics the effects of *ras* oncogene transfection
- Induces *c-sis* expression

PURITY: greater than 96 percent homogeneous by silver-stained gels, amino acid analysis and N-terminus sequencing.

ACTIVITY: Approximate ED_{50} of 1 ng/ml for the stimulation of colony formation of AKR-2B (clone 84A) cells in soft agar and 0.1 ng/ml for NRK (clone 49F) cells.

NATURE CLASSIFIED

Professional appointments — Research posts — Studentships — Fellowships — Conferences — Courses — Seminars — Symposia: **Back Pages**

Next week in *Nature*:

- Dwarf black hole at galactic centre
- CO_2 and vegetation
- Coulomb's law wanting
- Secondary antiprotons
- Palaeomagnetic measurement
- Continental growth
- Protein kinase C affects K^+ conductance
- *neu* oncogene
- Man's place among great apes
- Expression of cauliflower mosaic virus
- Advocacy in science

GUIDE TO AUTHORS

Authors should be aware of the diversity of *Nature*'s readership and should strive to be as widely understood as possible.

Review articles should be accessible to the whole readership. Most are commissioned, but unsolicited reviews are welcome (in which case prior consultation with the office is desirable).

Scientific articles are research reports whose conclusions are of general interest or which represent substantial advances of understanding. The text should not exceed 3,000 words and six displayed items (figures plus tables). The article should include an italic heading of about 50 words.

Letters to *Nature* are ordinarily 1,000 words long with no more than four displayed items. The first paragraph (not exceeding 150 words) should say what the letter is about, why the study it reports was undertaken and what the conclusions are.

Matters arising are brief comments (up to 500 words) on articles and letters recently published in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted.

Manuscripts may be submitted either to London or Washington). Manuscripts should be typed (double spacing) on one side of the paper only. Four copies are required, each accompanied by copies of lettered artwork. No title should exceed 80 characters in length. Reference lists, figure legends, etc, should be on seperate sheets, all of which should be numbered. Abbreviations, symbols, units, etc, should be identified on one copy of the manuscript at their first appearance.

References should appear sequentially indicated by superscripts, in the text and should be abbreviated according to the *World List of Scientific Periodicals*, fourth edition (Butterworth 1963-65). The first and last page numbers of each reference should be cited. Reference to books should clearly indicate the publisher and the date and place of publication. Unpublished articles should not be formally referred to unless accepted or submitted for publication, but may be mentioned in the text.

Each piece of artwork should be clearly marked with the author's name and the figure number. Original artwork should be unlettered. Suggestions for cover illustrations are welcome. Original artwork (and one copy of the manuscript) will be returned when manuscripts cannot be published.

Requests for permission to reproduce material from Nature *should be accompanied by a self-addressed (and, in the case of the United Kingdom and United States, stamped) envelope.*

BIO/TECHNOLOGY INVITES YOU TO ATTEND ITS

PREMIER CONFERENCE

BIO/TECHNOLOGY

LOOKS TO THE NEXT DECADE

January 20-22, 1986—New Orleans

BIO/TECHNOLOGY Looks to the Next Decade will go beyond most scientific symposia. First and foremost, the conference will bring together some of the world's leading authorities in molecular biology and process technology in a setting modeled after the very best of the invitation-only conferences. Everything is designed to provide a maximum exchange of ideas and information.

A look at the roster of keynote speakers, all leading researchers in their fields, demonstrates at a glance that only the highest level of scientific information will be presented.

To insure the greatest possible interaction and exchange, each afternoon will be devoted to roundtable discussions chaired by the keynote speakers, and featuring panelists of the highest calibre. There will be opportunity for all attendees to make brief presentations during these sessions, and participants are urged to bring their own slides.

If you want to get a jump on the ideas and techniques that will guide biotechnology through the '80s and '90s—this conference is for you.

Participation will be limited to provide maximum opportunity for fruitful exchange. So don't delay. Register now to guarantee your place.

CONFERENCE PROGRAM & SPEAKERS

JANUARY 20—MORNING

THE MOLECULAR BIOLOGY OF PLANTS AND ANIMALS: A VIEW FROM THE FRONTIER

SPEAKERS:

David Goeddel
Director, Molecular Biology, Genentech

Richard Flavell
President, Biogen Research Corp.

Norman Borlaug
CIMMYT, Mexico City and Professor, Dept. of Soil and Crop Science, Texas A&M

JANUARY 20—AFTERNOON

SEMINAR IN MOLECULAR BIOLOGY

PANELISTS

David Goeddel, Co-Chairman

Richard Flavell, Co-Chairman

Budd Colby
Director, Technology Development,
Triton Biosciences

SEMINAR IN AGRICULTURAL BIOTECHNOLOGY

PANELISTS

Norman Borlaug, Chairman

Robert Fraley
Manager of Plant Molecular Biology,
Monsanto

David Evans
Vice President for Research,
DNA Plant Technology, Inc.

Charles Arntzen
Associate Director of Central Research and Development,
E.I. Du Pont de Nemours and Co.

JANUARY 21—MORNING

COMMERCIAL PRODUCTION PROCESSES

SPEAKERS:

Malcolm Lilly
Professor of Biochemical Engineering, University College London

Robert Herschberg
Department of Process Development,
Genentech

Yukio Sugino, Director
Biotechnology Labs, Takeda Chemical,
Japan

Ephraim Katchalski-Katzir
Professor of Biophysics and Biotechnology, Tel Aviv University, Israel

Now You Have A Choice of Two Benchtop Ultracentrifuges

For spinning small samples at 100,000 rpm

For a decade, researchers have been using the economical little Airfuge® Ultracentrifuge to pellet microsamples quickly at high centrifugal forces. It accelerates to 100,000 rpm, pellets, and gently stops before a floor-model ultracentrifuge can even get to speed.

Now Beckman offers yet another advance in ultracentrifuge technology — the TL-100. This microprocessor-controlled benchtop model with refrigeration does a lot more than pellet. It can isolate plasmid DNA in a 2-mL tube using precious little CsCl. It makes rate zonal separations just like big ultracentrifuges but in 2.2-mL tubes in its own miniature swinging bucket rotor. It even offers a vertical tube rotor with 2-mL tubes.

Use the Airfuge for quickly pelleting small sample volumes and for special jobs like preparing particles for electron microscopy. Use the TL-100 for any other separation technique on microsamples. Save your floor-model ultracentrifuge for larger volumes.

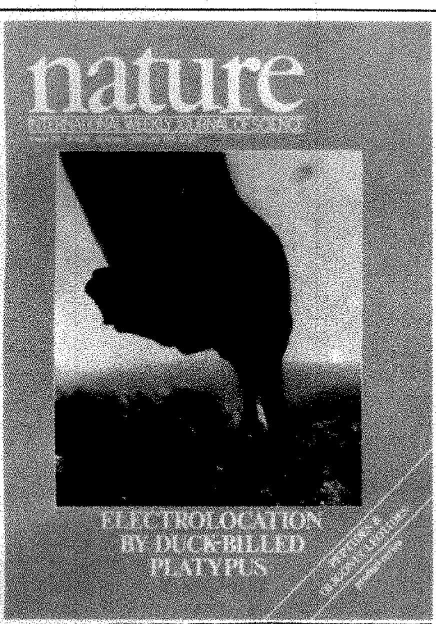
NATURE VOL. 319 30 JANUARY 1986



A trained duck-billed platypus attracted by the dipole field of a battery. During its dive the platypus closes its eyes, ears and nose by reflex action, relying totally on electrical somatosensory and chemical sensors in the bill. The battery, at a distance of 10 cm, sets up a field strength similar to that produced by the muscle potentials of live prey. See p.401. (Photo: G. Langer)

INTRODUC
THE RAPID RC
CUSTOM PE
FOR ANTIPEPTIDE ANTIBOD

CRB CUSTC
EXPRE

CRB have developed great experience in the **Selection** and
generation of **Antipeptide Antibodies** to oncogenes, growth
proteins etc., together with expertise in Peptide Conjugation T
and Assay Procedures.

As an addition to our existing services for molecular biology,
(2-3 weeks) for the custom synthesis of such peptides. These **Gu**
are supplied at **Low Cost** with **Comprehensive Analytical Da**
fast atom bombardment mass spectrometric analysis).

Peptide-carrier protein **Conjugates** may also be prepared ra
variety of methods directed to the production of more careft

Other CRB services include Hydrophilicity Analysis, Epitop
Antibody Specificities, synthesis of internally Radiolab
developing a New Immunisation Protocol for the h
antibodies.

For further details, or for any information c
of, synthetic peptides please cont
Research Director.

A Voyager 2 picture of Oberon, Uranus' outermost moon, taken from a distance of 410,000 miles. The colour was reconstructed from images taken through the narrow-angle camera's violet, clear and green filters. Features as small as 7 miles on the moon's surface are visible, as are several large impact craters. For more Voyager photographs, see p.453.

GUIDE TO AUTHORS

Authors should be aware of the diversity of *Nature*'s readership and should strive to be as widely understood as possible.

Review articles should be accessible to the whole readership. Most are commissioned, but unsolicited reviews are welcome (in which case prior consultation with the office is desirable).

Scientific articles are research reports whose conclusions are of general interest or which represent substantial advances of understanding. The text should not exceed 3,000 words and six displayed items (figures plus tables). The article should include an italic heading of about 50 words.

Letters to *Nature* are ordinarily 1,000 words long with no more than four displayed items. The first paragraph (not exceeding 150 words) should say what the letter is about, why the study it reports was undertaken and what the conclusions are.

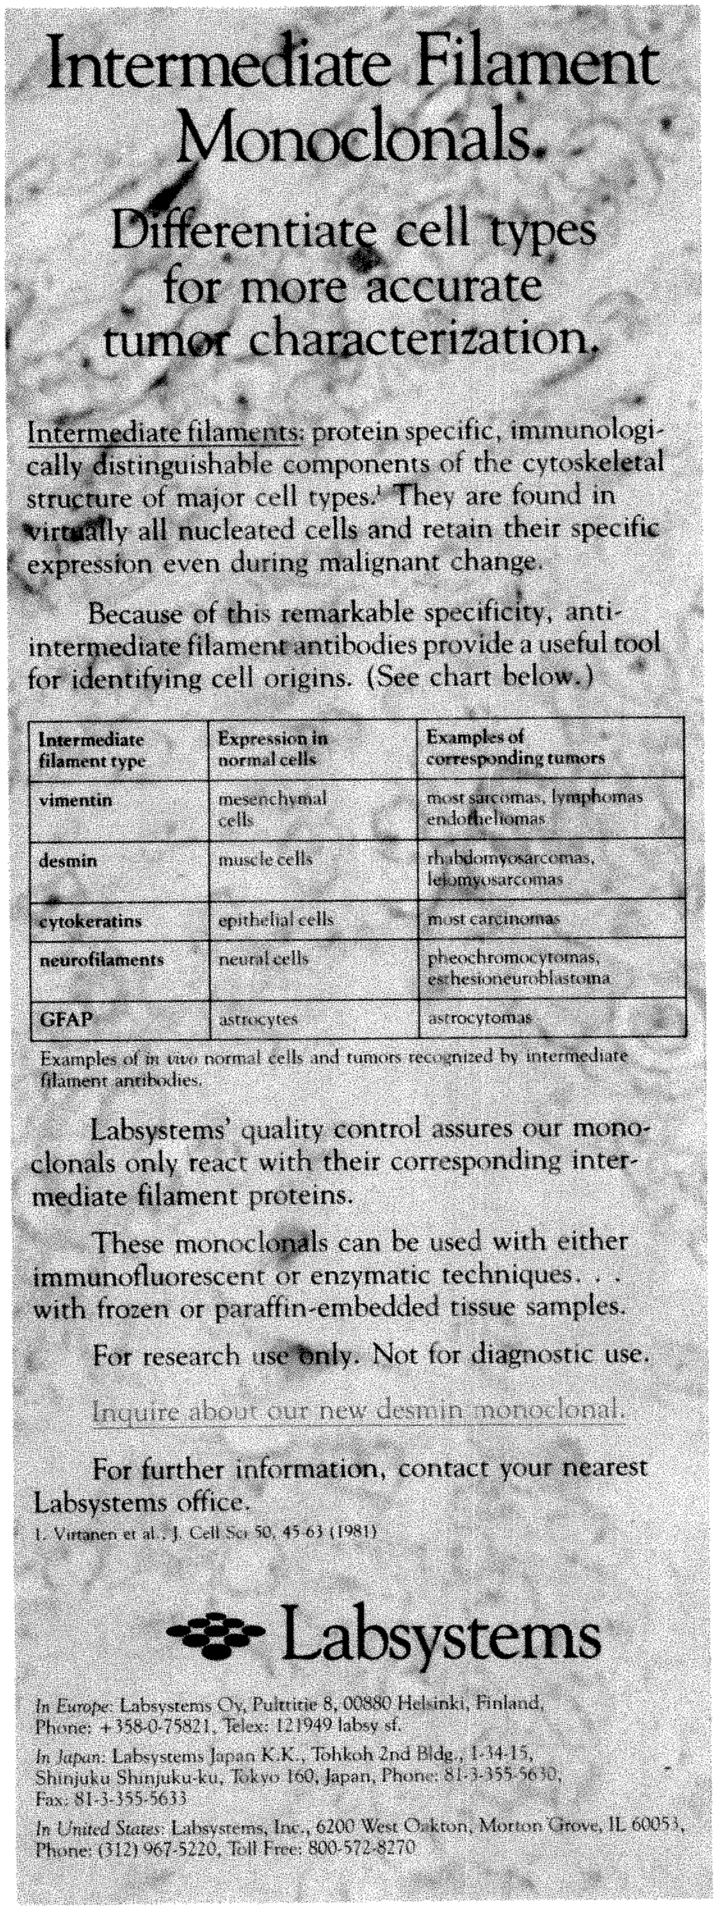
Matters arising are brief comments (up to 500 words) on articles and letters recently published in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted.

Manuscripts may be submitted either to London or Washington). Manuscripts should be typed (double spacing) on one side of the paper only. Four copies are required, each accompanied by copies of lettered artwork. No title should exceed 80 characters in length. Reference lists, figure legends, etc, should be on seperate sheets, all of which should be numbered. Abbreviations, symbols, units, etc, should be identified on one copy of the manuscript at their first appearance.

References should appear sequentially indicated by superscripts, in the text and should be abbreviated according to the *World List of Scientific Periodicals*, fourth edition (Butterworth 1963-65). The first and last page numbers of each reference should be cited. Reference to books should clearly indicate the publisher and the date and place of publication. Unpublished articles should not be formally referred to unless accepted or submitted for publication, but may be mentioned in the text.

Each piece of artwork should be clearly marked with the author's name and the figure number. Original artwork should be unlettered. Suggestions for cover illustrations are welcome. Original artwork (and one copy of the manuscript) will be returned when manuscripts cannot be published.

Requests for permission to reproduce material from Nature *should be accompanied by a self-addressed (and, in the case of the United Kingdom and United States, stamped) envelope.*



Intermediate Filament Monoclonals.

Differentiate cell types for more accurate tumor characterization.

Intermediate filaments: protein specific, immunologically distinguishable components of the cytoskeletal structure of major cell types.[1] They are found in virtually all nucleated cells and retain their specific expression even during malignant change.

Because of this remarkable specificity, anti-intermediate filament antibodies provide a useful tool for identifying cell origins. (See chart below.)

Intermediate filament type	Expression in normal cells	Examples of corresponding tumors
vimentin	mesenchymal cells	most sarcomas, lymphomas endotheliomas
desmin	muscle cells	rhabdomyosarcomas, leiomyosarcomas
cytokeratins	epithelial cells	most carcinomas
neurofilaments	neural cells	pheochromocytomas, esthesioneuroblastoma
GFAP	astrocytes	astrocytomas

Examples of *in vivo* normal cells and tumors recognized by intermediate filament antibodies.

Labsystems' quality control assures our monoclonals only react with their corresponding intermediate filament proteins.

These monoclonals can be used with either immunofluorescent or enzymatic techniques. . . with frozen or paraffin-embedded tissue samples.

For research use only. Not for diagnostic use.

Inquire about our new desmin monoclonal.

For further information, contact your nearest Labsystems office.

JOURNALS FROM MACMILLAN

NEW JOURNAL LAUNCHED DECEMBER 1984

☐ **PHARMACEUTICAL MEDICINE** Quarterly

Editor: R. N. Smith. Assistant Editor: P. J. Keen

"a quarterly journal, which includes papers on the validation of new and established methods of testing drugs in man written by investigators both inside and outside the pharmaceutical industry. It also provides a forum for the exchange of ideas about issues affecting drug development. These new developments merit support from all involved in the management, sale and use of drugs." ***Lancet***

☐ ***BRITISH JOURNAL OF PHARMACOLOGY*** Monthly

THE JOURNAL OF THE BRITISH PHARMACOLOGICAL SOCIETY

Chairman: J. F. Mitchell

Secretary to the Editorial Board: G. M. Lees

One of the top five most cited pharmacology journals in the world.

A vital source of relevant information for physiologists, immunologists, molecular biologists

☐ ***PUBLIC HEALTH*** Monthly

THE JOURNAL OF THE SOCIETY OF COMMUNITY MEDICINE

Editor: J. S. Robertson

From the beginning of 1986 Macmillan will be publishing ***Public Health.*** Now in its 100th volume, the journal publishes studies in preventive and social medicine and all aspects of public health and particularly welcomes reports of original epidemiological studies

☐ ***POSTGRADUATE MEDICAL JOURNAL*** Monthly

JOURNAL OF THE FELLOWSHIP OF POSTGRADUATE MEDICINE

Editor: B. I. Hoffbrand

A monthly compendium of current clinical research and practice invaluable to the graduate in training

☐ ***HUMAN TOXICOLOGY*** Bi-monthly

Secretary to the Editorial Board: P. Turner

Covers all aspects of human toxicology embracing both animal research with particular relevance to man and studies with humans

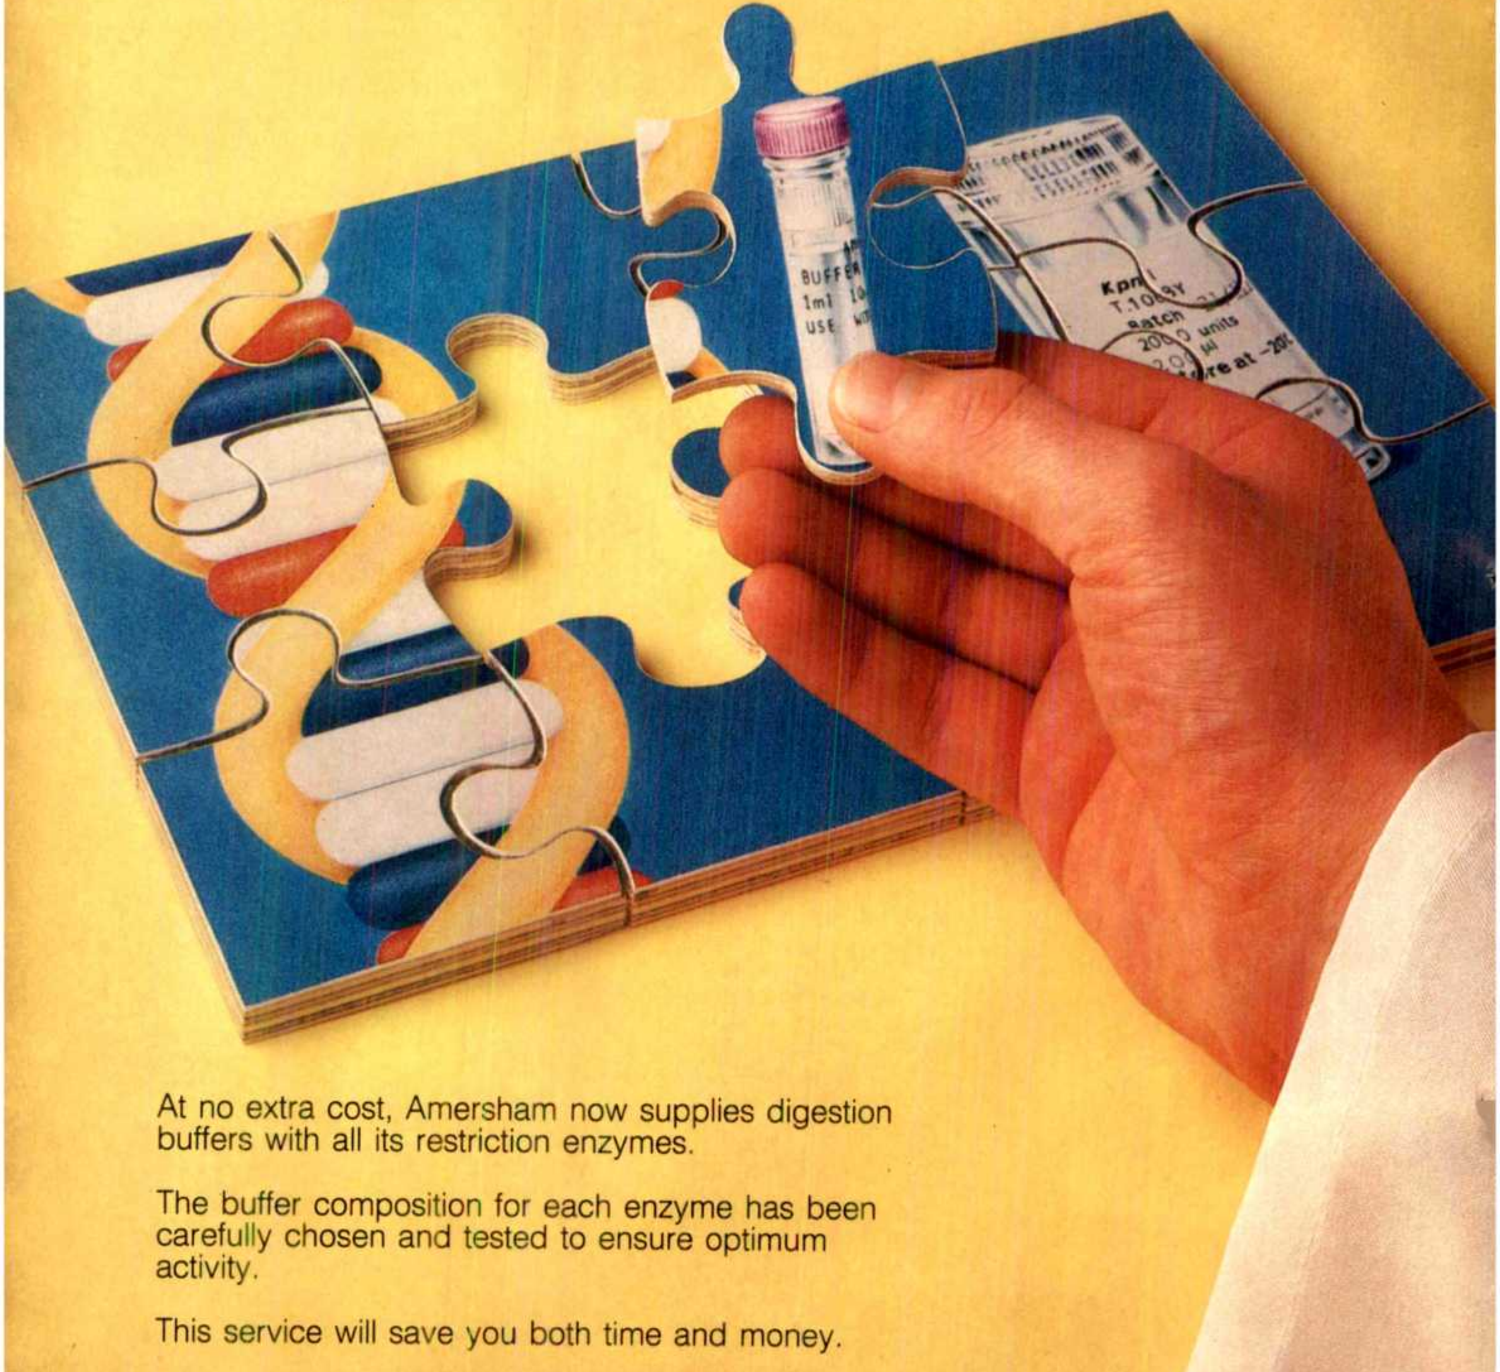
Amersham provides the perfect match



At no extra cost, Amersham now supplies digestion buffers with all its restriction enzymes.

The buffer composition for each enzyme has been carefully chosen and tested to ensure optimum activity.

This service will save you both time and money.

So when it comes to DNA cleavage, remember it's only Amersham who provides the correct buffer with each enzyme—a perfectly matched pair.

Who will regulate the bankers?

That financial institutions should be trustworthy is a necessary condition for their continued sponsorship of innovation. Banks, in other words, need laws.

Not so long ago, banks were the epitome of stability in society. Grave sober-suited men (there were hardly any women) would move around marbled banking halls confident that even if they were not much liked, they were at least respected, veritable pillars of society. Now all that has changed. On both sides of the Atlantic and in the Far East as well, banks have taken to going bust. Last year, there were more banking failures in the United States than in any previous year since the great depression. During the same year, in Britain, the Bank of England moved quickly to rescue from impending collapse the Johnson Matthey Bank. Why has there been this rash of banking failures? Do they matter? And, if so, what can be done to prevent them?

A bank is an institution that makes a business of looking after other people's money. It will borrow money from one group of people and lend that same money on to other people. Its lenders are recompensed by the payment of part of the interest the borrowers are required to pay; the remainder goes to the owners of the bank, a reward for their time, trouble and expense. A banking system is an essential ingredient of an industrial society; if people had no choice but to keep personal wealth in gold, hidden perhaps in a mattress, there would be no means by which one person's wealth could finance another's innovation. The social function of the banks is to make some people's personal wealth accessible to others who may make better use of it, the creation of credit as it is called.

The only other way of financing innovation so far devised entails the embodiment of most wealth in the state, and the subsequent investment of the same funds by civil servants, as attempted in countries such as the Soviet Union. In the West, technology as it has become is as much the creation of the banking system as of technologists. Certainly the collapse of the banking system would bring technology to a halt. One of the great conceptual developments of the past few years has been the discovery that all financial institutions that take in money from some people and lend it to others have exactly the same economic function as those formally called banks.

Fraud

Obviously, such a system is open to abuse, most simply by the crude device in which the bankers convert depositors' money to their own use, paying enough interest to keep the victims happy and being prepared to decamp when all the funds have gone. In most places, bankers who operate in this fashion are considered criminals, and may finish up in gaol. Others may run into trouble innocently, by lending their deposits unwisely, either because they too readily share their borrowers' optimism (which partly accounts for the troubles of banks in the US Middle West that, two years ago, found themselves over-committed to oil exploration) or because of unexpected changes in the economic climate. Between these extremes of fraud and innocence, the unhappy experience of the past few years has revealed a wealth of ingenious schemes by which bankers, in the pursuit of profit, can run into trouble. Lending money to borrowers unlikely ever to repay the funds may seem profitable until the period of the loan runs out.

Banks and other financial institutions are also vulnerable to fraud, by individuals or even other institutions. Embezzlement, the device by which bank officers siphon off deposits for their own use (often with the conviction that it can be repaid) was once the most common reason why some bankers would be drummed out of their community; it has become a means by which financial institutions can be busted, as with those sections of the Lloyds insurance market in London that have been affected by the scandals of the past few years. Among the tricks that institutions have learned to play on each other are the use of the same collateral to raise more than a single loan, one of the devices by which the Florida company EMS Securities kept itself afloat while insolvent until, last year, it collapsed, bringing down a string of Ohio banks with it. The collapse of the Singapore stock market in the past few weeks has been brought about by yet another device, essentially one by which present credit was traded against future obligations (which could not be met).

Fear

What now worries Western governments, and should worry the rest of us, is the fear that the financial troubles of the past few months will get out of hand. Governments are in a nasty fix. Having recognized that all financial institutions are banks of a kind, and recognizing the importance of banks as a means of stimulating economic activity, they have moved quickly to remove regulations preventing one set of financial institutions from competing with another. The technology the banking institutions have helped to stimulate has brought further complications; dealing in financial securities (debt obligations) has become literally a 24-hour business. The rewards of success are greater than ever. The risks of failure are similarly unprecedented, as is the suspicion that a large part of the debt hanging over the markets, the obligations of the debtor nations of Latin America in particular, may be worth not much more than the paper (or silicon) on which it is recorded. And the much-publicized misdemeanours of the heirs of the black-suited men of a previous generation has raised the question whether bank officers can be trusted with the future of the world's prosperity.

So enthusiam for deregulation is being overlaid by enthusiam for further regulation. In Britain, a curious situation has arisen. Since the early 1970s, successive governments have rightly encouraged changes of the rules by which institutions of different kinds must live. Competition among financial institutions has indeed increased, while London has strengthened its place on the international scene, roughly half-way between Tokyo and New York. Two years ago, the stock market (in exchange for the government's agreement not to pursue a complaint that its internal rules were restraints on competition) agreed to dispense with the most irksome of these restraints, the rules regulating those who may trade in stocks. The result now is that there are powerful and newly created financial institutions, many of them offshoots of conventional banks, waiting for the day next October, called the "big bang", when competition is to be free. The only certainty is that not all the hopeful institutions can hope to succeed, or even survive.

The dangers in such a prospect should be plain for all to see. The social function of the London stock market, like that of other stock markets, is to provide a means of buying and selling the debt obligations of governments and commercial companies, essential if lenders are to be persuaded to lend. But stockbrokers, with the help of banks of different kinds, also function as a means of bringing new money into the system, in which respect they function as if they were banks in the more familiar sense. The London stock exchange (like others) sets out to regulate the securities that may be bought or sold and even the terms on which trading is allowed, yet there is no means by which lenders (called investors) can be protected against their own poor judgement (nor should there be). But the unprecendented circumstances in which, later this year, much enlarged stockbroking firms will be fighting each other for business that will not expand overnight to match their ambitions are plainly full of risk; the London stock market (like others) maintains a fund to compensate investors who lose money when stockbrokers fail, but there are plainly arithmetical limits to what the collective power of commission-men can do to safeguard the assets belonging to those on whose behalf they deal.

That is only one of the reasons why the British government should be more active in the regulation of its financial institutions. The issue has been bubbling away for two years, since the publication of the report on the steps needed to safeguard investors by Sir Jim Gower. The government has already created a Securities Investment Board whose function will be to superintend the working of financial institutions other than banks (looked after by the Bank of England), the stock market (which superintends itself) and the Lloyds insurance market (which purports to do the same). While the new board will require all those who take in money to be registered, it will ordinarily agree that groups of like-minded institutions should look after themselves. Similarly, the supervision of ordinary banks by the Bank of England is to be overseen by another new board, but one nominated by the Bank of England itself. Before this intended legislation becomes law, it may easily be amended. It should be toughened, and for a simple reason.

However well-deserved may have been the reputation for probity of past bankers, the sanctions they used to apply to keep each other on the straight and narrow path no longer apply. A fraudster who knows that he can move easily from one financial centre to another will not be much deterred by knowing that he will be disinvited from the better golf clubs in the place at which his activities are first discovered. The financial community in Britain is nevertheless offended that there should be talk of explicit external regulation of its affairs, while the government is over-inclined to listen to these arguments. But in the long run, there will be no alternative to explicit regulation. The British government had better bite that bullet now, before too much damage is done. Financial institutions are too important to the economy to be left solely in the hands of financiers. □

OPEC is not yet dead

The oil producers will now be less powerful unless the oil consumers invite further discomfort.

OPEC, the Organization of Oil Exporting Countries, continues to exist, but only just. That is the simplest reading of the meeting at Geneva early in December, when the member states decided that they could no longer by *fiat* fix the world price for crude oil. This development has been on the cards for at least the past two years, for as long as OPEC's fixed price has been greater than the price at which oil was to be had on the Rotterdam spot market, and while OPEC members have themselves been selling oil at prices below the official price. So is it possible now to celebrate the end of an awkward period in the affairs of the industrialized West and then to forget?

That is what complacency suggests, but complacency is a poor guide. OPEC came into being a quarter of a century ago because the oil-exporting countries quite rightly tumbled to the fact that they were being exploited. In the 1950s, crude oil was being taken from Saudi Arabia at less than one US dollar a barrel, of which less than a half found its way to the government of that kingdom. During that period, in the United States, it was necessary artificially to prop up the price of domestically produced oil by means of cumbersome sponsored devices such as the Texas Railroad Commission, a federally sponsored carte. But OPEC showed its strength only in 1969, when Libya cancelled the concessions previously let to multinational oil companies, and began selling its own oil to those prepared to buy it. From that point, the developments of 1973, when the official price of OPEC's crude oil was multiplied roughly five times, were inevitable. The further but smaller increases of price in 1979, ostensibly compensation for inflation in oil-consuming states, were a proof that OPEC was still in a strong position.

What has happened since was also predictable. In the oil-consuming states, the intensity of energy consumption has decreased steadily and dramatically, partly because of greater efficiency but also because of the changing pattern of goods manufactured in the industrialized West. It could easily come about that energy consumption, and oil consumption in particular, will increase again if economic growth accelerates, but many old inefficient ways have probably gone for good.

But none of this implies that OPEC, too, has gone for good. In the long run, the present period of OPEC's weakness, brought about by the declining demand for oil by the industrialized economies and the success of exploration for oil (at OPEC's high price) elswhere in the world, has been accentuated by the urgent need of some oil-producing governments to maintain their oil revenues at the high levels to which they have been overfortunately accustomed. Iran and Nigeria, importunately compelled to sacrifice their long-term interests for the immediate need for cash, have done as much to weaken OPEC as the compensatory market mechanisms at work elsewhere.

For the years immediately ahead, the course of events is predictable enough. Now that oil prices have fallen (to not much more than $25 a barrel or $175 a tonne), the incentives to exploration will be diminished (but not much), economic activity in the industrialized economies should be stimulated (but, again, not spectacularly) and the price of oil will find a new level at which the interests of the producers and the consumers are balanced. But further ahead, early in the next century perhaps, there will be a different setting for the oil market. By then, no doubt, there will have been further important discoveries of oil in parts of the world still unexplored, so that the potential membership of OPEC will have been enlarged or at least changed (for some oil producers will also have used up their reserves). Similarly, there may then also be now unexpected developments in energy technology that could have transformed the pattern of consumption. But what will stand out, at the turn of the century, is that Saudi Arabia will almost certainly remain in the unique position it occupies at present, as the country most richly endowed with plentiful reserves of crude oil that differs in the most radical respect from that available elsewhere — its production cost is very much less.

This is the sense in which December's events do not spell the end of OPEC. Even if in the years ahead it is destined to become a not particularly congenial dining club, there is every reason to expect that the market for petroleum will change in such a way that Saudi Arabia will again be in a position to play a leading part in sharpening OPEC's teeth. For the oil consumers, the lesson should be clear. Whatever new discoveries there may be, and whatever the fluctuations of the price of crude oil, there are the strongest strategic reasons for strengthening the influences that have induced the energy economies of the past few years. Artificial restraints are inappropriate, as are subsidies of any kind. The better rationalization of industrial production internationally may be more important. Nobody wants OPEC to become a tyrannical influence on the world economy again, but the safeguards are in the hands of the oil consumers. □

Japanese public health

New campaign launched against hepatitis B

Tokyo

JAPAN'S Ministry of Health and Welfare launched the world's first public hepatitis-B immunization campaign on 1 January. Funds have been provided to immunize 10,000 babies each year identified as being at risk by the presence of hepatitis Be (HBe) antigens in their mothers.

The go-ahead for the programme follows by a few weeks the commercial release of hepatitis-B vaccines from two domestic manufacturers, the Kitasato Research Institute and Green Cross. A third manufacturer, the Chemo-thero Therapeutic Institute, will have a similar product available in May. Licences to produce the vaccines were granted in April after clinical trials were completed. The vaccines are derived from the plasma of hepatitis-B virus carriers inactivated by heat and formalin treatment and are essentially the same as those licensed in the United States in 1982.

Carrying out the programme is very expensive. Each of the three injections required costs around 5,000 yen (US$25) and this is added on to the high cost of identifying mothers whose babies are at risk. One thousand million yen ($5 million) has been allocated by the government for the first year of the campaign. Hepatitis B is a major public health problem in Japan not only because of the seriousness of hepatitis itself but also because it can lead to cirrhosis and cancer of the liver. Hepatitis-B virus infection has been linked to more than 80 per cent of all casses of primary hepatocellular cancer: the immunization campaign may thus fairly claim to be the first that might wipe out one form of cancer. Mother-to-child transmission of hepatitis B is the most important route of production of hepatitis B carriers; 85–90 per cent of babies borne to HBe-antigen-positive mothers will have become carriers by the time they are three months old. Clinical trials of the immunization method on 3,000 babies in Japan have already shown that transmission can be virtually wiped out.

Japan's selective immunization campaign is not, however, likely to serve immediately as a model for other countries. First, Japan is one of the few affected nations wealthy enough to bear the costs of immunization and with the expensive procedures for testing for HBe antigen established as routine at health centres. Again, although the overall frequency of hepatitis-B carriers is, at 2.6 per cent (rising to 5 per cent in some areas of Kyushu), quite high compared to Europe and North America, it is still sufficiently low that idenfifying those at risk is cheaper than a mass immunization campaign.

In the developing countries of Asia, the problems are of a different magnitude. In both Taiwan and Korea, around 15 per cent of the population are carriers and in mainland China around 10 per cent. Chinese officials say that the cost of vaccine would have to fall by one to two orders of magnitude before any mass immunization campaign could be contemplated.

Hopes for a fall in costs lie with the genetically engineered vaccines now just coming onto the market. The vaccines, produced by the Pasteur Institute and Genentech in mammalian cells and by Merck in yeasts, are still very expensive. But the potential market is huge and Japanese companies are in the race to produce cheap vaccines. **Alun Anderson**

Australian science

Radical shakeup planned

THE Australian Science and Technology Council (ASTEC), the world's most prolific source of recommendations on the management of publicly supported research, has advocated radical changes in the organization of the Commonwealth Scientific and Industrial Research Organization (CSIRO). The recommendations are put forward by a subcommittee of ASTEC under its chairman, Professor R.O. Slatyer of the Australian National University, Canberra.

In a report* to the federal prime minister published at the end of last year, ASTEC advocated the replacement of the present top management of the organization, called the "executive" and consisting of three full-time and two part-time members, by a board of seven part-timers and a single full-time official, which would be the source of research policy for the organization. The most startling aspect of this proposal is that the full-time official, to be called the Chief Executive, would be appointed by the board (rather than by the government) and would be liable to dismissal by the board.

According to the report, the chief purpose of the proposed changes would be to ensure that the lines of responsibility for research policy and for management within CSIRO are unambiguous. The Slatyer committee has considered but rejected arguments that CSIRO should be split up into separate organizations responsible for research in different fields, on the grounds that Australia needs a strong central (and flexible) research organization but the committee urges that CSIRO's strategy should be more closely directed towards the needs of existing and emerging industries, saying that CSIRO programmes exclusively concerned with basic research should be hived off to other institutions, most probably universities, "perhaps in conjunction with a scheme to identify national centres for research in which a number of universities might participate".

The starting point for many of the Slatyer committee's proposals is a sense of regret that the last reform of CSIRO eight years ago has not produced the benefits expected of it. The report says that CSIRO's advisory council has not been able to influence policy as intended (and that it should be abolished), and that the same conclusions apply to the state and territory committees that at present formally have a role in guiding research policy. The Slatyer committee is especially regretful that the 1977 reform that grouped CSIRO research laboratories (called divisions) into three institutions, each with a separate director, has blunted rather than strengthened the links between top management and the divisions.

Although the Slatyer report does not say so explicitly, its recommendations reflect the evolution of Australian research institutions and in particular the increasing strength of the universities in research. But the sustained emphasis in the Slatyer report on the need that CSIRO should concentrate its efforts and resources on providing assistance for industry (including the traditional industries of agriculture and mining) will, if accepted, bring about a considerable change both in the pattern of research at many of the well-established research divisions and in the ethos of CSIRO as Australia's chief employer of those bent on a career in research.

On the last point, the report says that CSIRO should give up its now common practice of employing most of its new recruits on indefinite contracts (there is also at present a one-year probationary contract) and that it should instead switch to a system in which an initial period of employment on a short-term contract would be the general rule, with an understanding that only a proportion of those thus hired would win permanent appointment. The committee says this pattern would, among other things, serve to provide opportunities for postdoctoral scientists, especially those returning from abroad. □

Remote sensing

US agencies blamed for muddle

Washington

An outspoken study of the "crisis" in the 13-year-old US Earth remote sensing programme by the National Academy of Sciences has concluded that US pre-eminence in the field is now seriously threatened by "not-so-benign neglect". The academy says that substantially increased government resources will be needed if the potential of the technique is to be realized, and knocks some agency heads together for letting the area fall into disarray.

The academy's report emphasizes that the present situation is urgent. The only civilian Earth remote-sensing satellite in service, Landsat 5, is expected to fail before private industry can launch a replacement. No improvement is likely unless the government increases the $250 million ceiling it has placed on remote sensing while the programme is being transferred to the private sector.

Although negotiations with an industrial consortium to take over the programme are at an advanced stage, there are still no definite arrangements for the future, and during the probable hiatus in the US service, the French company SPOT (Systeme Probatoire d'Observation de la Terre) can be expected to secure a large part of the market for remotely-sensed Earth data: although customers would prefer continuity of data, SPOT's data will be available and will have some technical advantages.

The academy's report* was produced by its research arm, the National Research Council (NRC), under the chairmanship of George Harter. The report has been more than two years in preparation and seems to have engendered some controversy: an earlier draft by a specially appointed committee was rejected by NRC's Space Applications Board, which then set about producing a better version. The work of the earlier committee is acknowledged only in passing.

NRC is enthusiastic about the ultimate potential of data sensed from space, while pointing out that data must in future (not as at present) be made available to users in processed form if they are to be saleable products. Oil companies, which now use remotely-sensed data for prospecting, have spent years and large research budgets in discovering how to use it. (Oceanographic remote sensing, according to NRC, should remain within the government as a "public good" service.)

Although NRC supports the government's basic strategy of turning Earth remote sensing over to the private sector while keeping meteorological satellites under its own wing, it is harsh in its criticism of how the strategy was carried out.

NRC stresses that technical problems are no part of the reason why the programme has done so badly. Rather, parochialism is to blame: the programme fell between the twin stools of the National Aeronautics and Space Administration (NASA) and the National Oceanic and Atmospheric Administration (NOAA).

Although the two agencies worked together for many years on remote sensing, after NOAA was officially placed in charge of the programme and NASA faced a budget crisis in the early 1980s, NASA threw the ball over to NOAA, which was apparently unready to catch it. Part of the reason, according to NRC, was NOAA's disadvantageous and often-criticized bureaucratic niche within the Department of Commerce. NRC accordingly recommends that NOAA be found a more suitable home.

Even if NOAA stays where it is, however, NRC is not so pessimistic as to believe the two agencies could never again work together constructively. NRC wants to abandon the present arrangements whereby institutional rather than technical considerations dictate what sensors are flown on a given spacecraft, and proposes a single coordinated effort, with NOAA remaining in charge of applied and market research for Earth data, and NASA providing technical support for the development of new sensors, for example. Finally, NRC tells the two agencies in future to allow each other to use space on their platforms and also to make this available to industry.

French science

CNRS faces political change

Should the Centre National de la Recherche Scientifique (CNRS), the principal French research council, be split up? This seems to be the question of the month in right-wing scientific circles in France, where the general election due in March is expected to return a government of the right. It is difficult to establish exactly where the idea comes from, although *Le Monde* picks on "sources close to Jacques Chirac", the mayor of Paris, expected to become France's next prime minister.

CNRS has had to contend with some criticism of late. The council is certainly big, supporting more than 10,000 academics in disciplines from physics to history, and its multidisciplinary nature has given it considerable flexibility in meeting the challenge of new sciences such as materials, microelectronics, robotics and biotechnology. But in responding to these new goals and in its policy of "*overture*", openings up the hallowed halls of academic institutions to the public, to industry and to other research bodies, CNRS "has changed profoundly" over the past 3–4 years, says its director-general Pierre Papon.

In so doing CNRS may have created enemies, particularly among more traditional academics used to the old somewhat feudal continental system of professorial fiefdoms that were once prevalent in France. CNRS has attempted to cross these barriers where they still exist — Papon still feels it necessary to preach the values of the British and US departmental system — and has also used its budgetary muscle, in concert with the ministry of education, to concentrate resources on priority areas. The prospect of a right-wing government has given some of those affected a chance to complain, and there is a growing clamour in France for a return of power to the professor, at the expense of that of the science political apparatus such as CNRS. A fragmentation of CNRS into disciplinary subsections would clearly serve this cause well.

To confuse matters, however, the present research minister in the socialist administration, Hubert Curien, speaking just before Christmas at a prize-giving at CNRS, was ambiguous in his reply to criticisms of the centre. He described the criticisms as "a typical French exercise in self-flagellation", and said that if CNRS did not exist, he would have to invent it; but he also said that "one must not be deaf to criticism" and talked of "a new mode of scientific organization" in "networks" of projects rather than isolated grants.

In the circumstances, one might expect M. Papon to feel somewhat isolated and exposed, but he finds no policy conflict with M. Curien. "Networks", for example, correspond to his own concept of interdisciplinarity. And moreover Papon was re-appointed for a second three-year term of office in October. He fully intends to continue his work under a new government, "unless it shifts policy by 90 or 180 degrees". Also, Papon's appointment was made by the President of France, and François Mitterrand does not face re-election until 1988. Papon also believes that "no responsible government could contemplate a dismemberment of CNRS", or retreat from the present government's policy of harnessing science for the economy, of which he himself has been a major architect. By the middle of the year, when a new government will be preparing its budget and policies for 1987, he should know if he is right.

Robert Walgate

Japanese communications

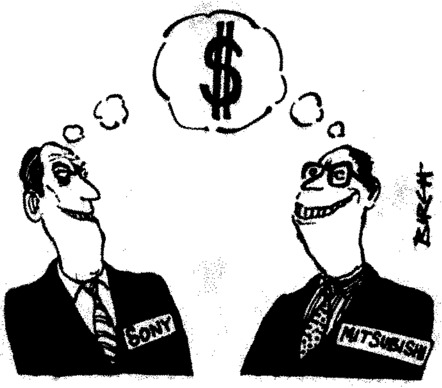
What band-rate for psi?

Tokyo

WHEN it comes to new methods of telecommunication, Japan's Ministry of Posts and Telecommunications believes in looking at even the long shots. The ministry's fanciful new "Research Committee on Future Telecommunications Media" is, among other things, to look into the prospects for telepathy as a communications medium.

The new eight-member committee has been established on the recommendation of a private advisory panel to the Minister of Posts and Telecommunications. It will be headed by Shigemichi Sonoyama, vice-president of the National Space Development Agency, and to add weight to the panel's discussions, another of its members is Tadahiro Sekimoto, president of the giant electronics company NEC.

Japan is not, of course, the only country in the world to think of the potential of telepathy; it has long been rumoured that the Soviet Union is taking the subject very seriously. But perhaps this is the first time that a posts and telecommunications ministry has taken up the idea. True to Japan's vigorous commercial spirit, the ministry has in mind practical application. An attractive feature of telepathy is that transmission is instantaneous, or so some claim. Dr Ootani, a psychologist at the Self-Defence Forces University, will be the principal scientist to investigate "superhuman abilities", although anyone with such abilities might be expected to avoid research panels and the possibility of being turned into a kind of living telephone exchange.



Telepathy will not be the only new telecommunications medium to be investigated. One professor from Kanagawa University will take a look at the potential of neutrinos. And another professor from Tohoku University will assess gravity waves, even though ministry officials agree that their existence is scarcely more certain than that of telepathic waves. Backing up their investigations are experts on brain physiology, electrical communication and computer intelligent management systems.

The committee is expected to hold four meetings by the spring for an initial exchange of views. Although the hopes of practical application of the new media might seem very far off, the ministry says it is not "too early to start study".

Red greens on Yellow River?

A BELIEF is growing in China that the proposed hydroengineering works on the Yangtze (Yellow) river will "spoil the scenery", the New China News Agency reports. But an unnamed official of the Yangtze river valley planning office maintains that construction of the proposed hydroelectric power station, which will substantially raise the water level in the Yangtze gorges, will not greatly harm the scenery. In fact the authorities are looking forward to improved amenities and, according to a planning office spokesman, "some new scenery will emerge".

The purpose of the project is threefold. The hydroelectric plant will have a capacity of 13 m kWh, said the spokesman, and will supply power to cities as far away as Beijing, Tianjin and Tangshan in the north, Shanghai in the east, Canton in the south, and Sischuan in the west. The new, higher water level will submerge more than 90 per cent of the dangerous shoals in the three gorges, thereby reducing hazards to navigation and increasing the number of vessels that can safely be carried on the middle Yangtze and the Chuan river, with a substantial saving in the cost of transport.

At the same time, flood control measures in the three gorges will substantially reduce the risk of flooding to the Dongtin Hu, Poyang Hu and Jianghan plains, densely populated areas which are China's commodity grain and cotton base. At present, more than 1 million people, the spokesman said, are needed to protect the existing dykes during the flood season each year, and according to archives going back to the end of the Han dynasty, some 2,000 years ago, there was major flooding until the beginning of this century in one year out of ten.

What form Chinese concern over the three gorges has taken is unclear. There is no suggestion of mass protests, but anxiety is clearly sufficiently acute and widespread for the planning office to find it necessary to issue a statement to reassure the public.

Vera Rich

Space science

British head for French lab

FRANCE is building a new £4-million laboratory for space sciences at the Université de Paris Sud (Orsay), and has attracted a leading British space scientist as its first director.

But Dr Alan Gabriel, now head of the space and astrophysics division of the Rutherford Appleton Laboratory near Oxford, who will direct the new Institut de Physique Spatiale d'Orsay (IPSO), says he does not feel part of a brain-drain. "I don't want to be negative about British space science", he said. "It's not true to say things are much better in France than they are here." The new British National Space Centre for the coordination of the UK space effort "offers most exciting possibilities" and it was "not at all" true to say British space science is not well-enough supported. Moreover space science is international, and Gabriel expects much cooperation between IPSO and his British colleagues.

However, Gabriel implies that he feels more cramped at the Rutherford Appleton Laboratory than he expects to be in Paris. Gabriel's present division of around 150 is merely one part of a 1,500-strong multidisciplinary laboratory; in Paris, IPSO will be no bigger than the space and astrophysics division but it will be independent, except for some support from the research councils and the university. "I shall be able to play a more creative role", Gabriel says.

At the new Paris laboratory, two-thirds of the staff will come from an existing French group housed in an overcrowded old laboratory in nearby Verrier-le-Buisson. The Laboratoire de Physique Stellaire et Planetaire has experiments on both the European and Soviet Halley probes (Giotto and Vega).

The new IPSO will also form a focus for a number of space science groups now scattered around the Paris area, and will take advantage of the proximity to LURE, the Orsay synchroton radiation source, for calibration of optical instruments from the X-ray region to the visible.

IPSO's initial research programme will concentrate on solar physics, infrared studies of the interstellar medium to shed light on mechanisms of star formation and Solar System studies including dust, comets and asteroids. (France is planning for a mission to the asteroids either within the European Space Agency or bilaterally with the Soviet Union.) Gabriel is also interested in developing a capability at IPSO for X-ray astronomy. He expects IPSO to become one of the major centres for space sciences in France.

Robert Walgate

Argentine science

Slow return to openness

Buenos Aires

ARGENTINE science is recovering slowly from the traumas of the past decade. In contrast with 1973, on the eve of the return of Peron, and 1979, after the military had finally repressed the opposition, it is evident that the morale of the people has been uplifted and that there is a strong desire for political stability under democratic rule.

The severe repression by the military dictatorship afflicted all scientists, depriving many of their jobs and some of their lives. One biochemist, apparently considered too outspoken, had a bomb planted in his house and telephone threats which compelled him to leave his university and to move with his family to a remote part of Argentina.

Another outspoken biochemist became a victim of the mindless repression apparently only because he was Jewish. His home was visited one day at five in the morning by men in plain clothes, who had come to arrest him. Fortunately, his wife's mother answered the door and screamed out that the men were thieves. So he escaped with his pregnant wife and young children over the roof tops.

The Israeli government, to its honour, acted as a Scarlet Pimpernel by providing passports for such refugees, irrespective of their religion; a general escape route was organized with the cooperation of the Belgian airline Sabena.

The exodus of Argentine scientists during the repression and their enrichment of the culture of other countries has been documented by Budiansky (*Nature* **311**, 201; 1984). Few of those expatriates have yet returned, probably because they cannot afford to; salaries in the universitites and government institutes remain depressed. Industrial salaries are relatively remunerative, three or four times those of academics. The low salaries in the state sector (see Budiansky's article) and the general economic malaise are professional people's chief preoccupation.

In the aftermath of the repressions, demands for retribution continue, but scientists are divided. Some, partly out of self-interest or envy, are accusing those who prospered under the military of criminality; others, including many who suffered under the despotism, support the call for a "full stop" to recrimination.

In the universities, a commission is examining the credentials of all professors appointed during the past 20 years, when the normal procedures for appointment were suspended. This is time-consuming for university staff and probably diverts attention from the need to renew the resources of the universities so as to meet the challenges of the future.

Argentina, in common with the developed countries, has greatly expanded its university system in the past two decades. (Cordoba, founded about 1650, is probably the oldest university in the Western Hemisphere.) Although the old universities are still dominant, such extra resources as there have been seem to have been concentrated on the new universities, so that there has been little renovation of the older universities, which are now dilapidated and inadequately equipped to strengthen or maintain their position as centres of science.

Nevertheless, scientists are pressing on in reasonably good spirits, although they seen no way out of the impasse caused by Argentina's economic problems. Subscriptions to journals have been cancelled wholesale; support for assistants has to come from professors' personal salaries. Buildings are in an appalling state, but all new building schemes have been frozen by the government.

There is a lack of campuses in the older universities, so that departments are widely scattered, and thus isolated from interaction with others and prevented from sharing equipment, libraries and overheads generally. Apparently, the authorities in the past have been suspicious of campuses as foci of political action by students. Surely such fears of criticism could be abandoned by the democratic government, even if the concentration of resources in campuses will have to be a long-term aim.

One move towards the concentration of resources was the inauguration of research centres by the national research council, CONICET. Buildings, staff and equipment were funded on a modest scale, but again these are dispersed and isolated. They have successfully encouraged good basic science, but now the government intends to transfer them from CONICET to the universities, which leaves researchers fearing that their centres will be reduced to a state of academic deprivation. Integration of the centres, with protection of their resources, is essential if their work is to expand.

In the biosciences, it is striking that, as elsewhere, the emphasis is now heavily on technology. The size of the Argentinian agricultural industry offers much scope for biotechnology to improve plant and animal crops, and eventually to exploit the arid regions and their solar energy. As in Brazil, 10–15 per cent of ethanol must be added to motor fuel to promote the exploitation of sugar by fermentation. Health care products are being developed through innovation in biotechnology. For instance, the Polichaco pharmaceutical company has announced a contract worth US$3 million to supply to Brazil diagnostic reagents for pregnancy testing. Excellent molecular biology towards characterizing the virus of Argentinian haemorraghic fever is being done at the University of La Plata, in laboratories which in Britain would be condemned as unsuitable. With resignation, the researcher says, "This shows that expensive facilities are not essential for success in molecular biology".

The government has set up a committee to develop a policy for biotechnology, and many groups seem to be competing for access to any funds that may be made available. But the government is still searching for a formula to define biotechnology. Yet a policy is needed urgently because of the momentum of research in this field elsewhere in the world and to offer the Argentinian scientists the opportunities they deserve.

Academic scientists have even begun to entertain the idea of obtaining support from industry and other entrepreneurs, but this approach may need legislation; the universities have traditionally prevented academics from having links with industry.

The transfer of technology from university to industry is beset with difficulty. In the fermentation field, despite its rapid expansion to produce ethanol, there is a marked reluctance by industry to take advantage of scientific innovation which Argentine scientists are developing, even in ethanol fermentation.

Remedies may yet emerge from the changing politiacal climate. Both the radical party government under Alfonsin and the recent Austral currency reform seem to be winning confidence. It is a pity that the Falklands (Malvinas) problem remains unsolved. The slogan "The Malvinas islands belong to Argentina" remains conspicuous in public places, even though serious comment recognizes the historical realities and the need for flexibility in Argentinian policy.

There is also a new spirit of cooperation in South America. Chile and Argentina have settled their territorial disagreement and, in the past weeks, there have been agreements between Argentina and Brazil and between Chile and Peru on friendship and cooperation.

The lack of normal relations between Britain and Argentina continues to affect trade. For instance, the supply of radioactive chemicals from Britain has been made difficult. One molecular biologist has resorted to making his own labelled nucleotides, with a cost saving of over 80 per cent on his reckoning if technician's time is discounted. There is an historical affinity between Britain and Argentina that surely requires Britain to settle its differences with Argentina with chivalry and thus to help ensure that despotism never returns there again.

S.J. Pirt

Laboratory animals

US protection act approved

Washington

SHORTLY before its Christmas break, the US Congress passed legislation supported both by animal welfare campaigners and by researchers' organizations designed to improved standards of care for laboratory animals. The Improved Standards for Laboratory Animals Act requires painful experiments to be justified to a committee that includes at least one disinterested member of the public charged with ensuring that pain and distress are minimized.

The new act was introduced by Senator Robert Dole (Republican, Kansas) and Representative George Brown (Democrat, California) with 136 co-sponsors. Animal welfare workers, chiefly the Society for Protective Animal Legislation, worked for two years with researchers' organizations to find acceptable compromise provisions. The bill as passed was supported by, among others, the America Society for the Protection of Cruelty to Animals, the Humane Society of the United States, the American Physiological Society and the Association of Professors of Medicine.

The chief effect of the new act is to require the creation of Institutional Animal Committees that must include one external member; at present, many but not all institutions which carry out research on animals have such committees. The committees will be required to conduct semiannual inspections of research facilities and to report violations of regulations to institutional and federal authorities. The Secretary of Agriculture is empowered to promulgate regulations on care, treatment and practices to minimize pain and distress, but not on the conduct of experiments.

The new act also requires institutions to provide training in the humane treatment of animals, encourages alternatives to animal testing where possible and requires principal investigators to certify that alternatives have been considered. Exercise for laboratory dogs, use of anaesthesia with paralysants and limitations on repeated major operations on the same animal are also specified.

A new information service at the National Agricultural Library is established under the act, in order to minimize unintended duplication of experiments, and both federal and private laboratories are subject to its provisions. Although the act makes clear that experimental protocols will be respected, it is required to suspend federal support if an agency determines that animal care in a particular project has been persistently unacceptable.

Tim Beardsley

Bhopal disaster

India blames Union Carbide

New Dehli

INDIA's official report on the events leading to the Bhopal disaster last year says that about half a tonne of water had entered the tank containing methyl isocyanate (MIC), thus confirming the findings of Union Carbide. But the report says that the chemical reaction leading to a catastrophic increase of temperature was caused by contamination of the tank by metal ions, which acted catalytically.

The report is the work of a 16-member committee led by Dr S. Varadarajan, the chemist who is now the secretary-general of the Department of Scientific and Industrial Research. It specifically disputes Union Carbide's claim that entry of large quantities of water alone was responsible for the ghastly accident on 2 December 1984, saying that the runaway reaction leading to a rapid rise of temperature and pressure in the storage tank could have been triggered by water only if the MIC inside the tank had also been contaminated with metallic impurities.

The report, by implication, rules out sabotage, alleged by Union Carbide, and instead puts the blame on the US company for its choice of unsuitable corrodable materials for the piping thought to have been the source of the contamination.

Varadarajan's committee reached its conclusions on the basis of experiments carried out on a second undamaged storage tank at Bhopal. The experiments included heating MIC alone and reacting it in the presence of water, chloroform and traces of ferric salts and sealed containers at temperatures up to 250 degrees centigrade. These simulations yielded all the twelve or so different types of solid residues found inside the damaged tank.

Based on these experimental data and an actual inventory of the tank residues, it was estimated that 12,087 kg of MIC and 595 kg of chloroform (used as a solvent) reacted with 512 kg of water, producing enough heat to vapourize the remaining 28 tonnes of MIC in the tank. The report says that the escaped gas also included 80 kg of ammonia and 1.25 tonnes of carbon dioxide.

The Varadarajan report has incidentally put to rest the controversy over whether the gas that leaked was MIC, cyanide or both. Union Carbide had from the beginning insisted that cyanide was not present, but Indian doctors who carried out autopsies on gas victims suspected otherwise. The report agrees with Union Carbide on the basis of the experimental evidence it has collected.

The most important finding of the Varadarajan committee relates to the role of water. Union Carbide maintains that the runaway reaction was due to the addition of large amounts of water to MIC containing chloroform. The Indian report says that ingress of 500 kg of water would at best have consumed four tonnes of MIC and raised the tank temperature to just 70 degrees centigrade, below the boiling point of MIC (at the safety valve pressure). The report also says that chloroform could not have catalysed the reaction below 200 degrees centigrade, whence the conclusion that some other catalyst must have been involved.

From the products of tank residues, calculated heats of chemical reactions and the extent of bulging in the tank, the committee estimated that the tank reached a temperature above 250 degrees centigrade. According to the report, only "the onset of metal-ion catalysed polymerization of MIC" could account for this rapid increase of temperature.

The Varadarajan committee says that the metallic contaminants (iron and sodium) came from corroded pipes and the tank itself and catalysed the trimerization of MIC. Subsequent entry of water hydrolysed the MIC, producing heat and carbon dioxide and allowing "trimerization to take off with explosive violence".

In support of this theory, the report lists iron, sodium, chromium and nickel among the metallic contaminants found inside the exhumed tank. Sodium was present at a level of 60 p.p.m., equivalent to 25 litres of 5 per cent sodium hydroxide. According to the report, the contaminants most probably came from tank accessories made of materials such as carbon steel and copper.

The source of sodium is identified as the vent gas scrubber. One source of iron was found to be the tank itself, probably released as ferric iron as a result of corrosion caused by hydrochloric acid formed by the hydrolysis of phosgene.

Exactly how the contaminants and half a tonne of water came to enter the tank, the report can only guess. Indirectly, the report rules out sabotage by the argument that while it may be easy to pour water into the tank, a saboteur would not know the role of metallic contaminants.

The report concludes that the gas leak would have been avoided had the 42 tonnes of MIC been stored in several small steel drums. "The needless storage of large quantities of MIC for long periods, as well as insufficient caution in design, choice of materials for construction and provision of measuring and alarm instruments, together with inadequate controls on systems of storage and quality of stored materials as well as lack of necessary facilities for quick and effective disposal material exhibiting instability led to the accident."

K. S. Jayaraman

AIDS in the human brain

THE causative agent of acquired immune deficiency syndrome or AIDS (variously known as LAV, HTLV-III or ARV virus) is akin to the lentiviruses[1]. It would appear, on current estimates of AIDS virus prevalence in the US population (about 0·5 per cent), that between 10^5 and 10^6 persons may develop lentivirus-like encephalopathies during the next fifteen years. When other animals are infected with similar lentiviruses (maedi–visna virus in sheep), the disease is progressive and fatal, with an incubation period of one to six years. The duration of AIDS encephalopathies already known in humans is not well established but may range from one to 14 years.

The similarities between the two diseases and their causative agents are established experimentally. Both of them, RNA retroviruses, are integrated into the genome of the host's cells as proviral DNA. Efforts to treat the viral DNA must include protection for the host's DNA, a task of which we are at present incapable. Both AIDS virus and the lentiviruses possess the properties of "antigenic drift", lessening the likelihood of a vaccine as we now understand vaccines. Thus, the burden of disease control falls on epidemiology and prevention.

The implications of such a large number of men, women and children with progressive disease for the economy, health care system and emotional state of society are unprecedented. The scientific necessities, the need to develop strategies for dealing with a new type of human infection and producing a lifetime viraemia pose scientific puzzles of dizzying proportions. Even if my estimates of clinical neurological disease are in error by one or more orders of magnitude, the tragedy is still shocking, especially as it comes on top of the already manifest deaths due to AIDS immune suppression. If AIDS is a lentivirus disease, the immune-suppressed AIDS patients may be only the tip of the iceberg.

The threat of AIDS as a lentivirus disease should motivate politicians, public health workers and scientists to establish a unified plan for AIDS prevention on local, national and international scales. Since the mechanics of transmission of AIDS-lentivirus are known, the great risk associated with anal intercourse, promiscuous heterosexual encounters, blood to blood contact and the use of shared drug injection paraphernalia must be explained in the most specific terms to all levels of society. Those already infected must be included in the strategy. Universal blood testing should not be ruled out. If AIDS is a lentivirus epidemic, to err on the side of caution would be prudent.

Earnshaw's theorem

SIR—This theorem is not often mentioned in scientific journals. It denies the possibility that an electric charge can be held stable solely under the electrostatic influence of other electric charge. It was used in a recent letter (*Nature* **317**, 208; 1985) to refute a case put earlier by Berezin (*Nature* **315**, 104; 1985). It is as well to keep in mind that the Reverend Samuel Earnshaw developed his theorem with an eye to the constitution of the aether as a medium comprising a structured system of electric charges, separated by what, presumably, would be regarded as a truly void state of the vacuum. The theorem fails if the charges permeate a charge plenum or continuum having a charge density, because displacement can then be subject to a linear restoring force rate, owing to interaction with this continuum.

We have now come to accept that the vacuum medium does have some rather special characteristics and a possible structure, so it is not unlikely that it comprises electric charges permeating a charge plenum, notwithstanding the Earnshaw theorem.

If this is the case, then the theorem cannot even be applied without some reservation when considering the mutual stability of charge in matter. The support for the structured vacuum is enhanced by the related theoretical derivation of the fine-structure constant in terms of the geometrical features of an electrical charge system neutralized by a charge continuum. A value of the fine-structure constant in matching accord with its measurement at the level of one part in ten million has recently been reported from such analysis (*Phys. Lett.* **110**A, 113; 1985).

Price of star wars

SIR—R. V. Harrowell (*Nature* **317**, 470; 1985) criticized the proposed Strategic Defense Initiative on the grounds that if it is successful it will supposedly release deadly amounts of unexploded plutonium into the atmosphere.

Let us compare the radioactivity of this plutonium with that of the radioactive material already present in the air. According to that arcane source of data, *The Handbook of Chemistry and Physics* (66th edition), the atmosphere masses 5.136 hexillion grams, its mean relative molecular mass is 28.966, and the molecular fraction of radon is one part per hexillion. If we combine this information we see there are 0.18 moles of radon in the atmosphere. The half-life of radon is 3.82 days and that of plutonium is 24,110 years; radion is therefore 2.3 million times as radioactive as plutonium. The equivalent of 400,000 moles (about 100 tons) of plutonium is already present in the air in the form of radon. We can compare that with the mass of 5,000 warheads at 10 kg of plutonium each, that is, 50 tons.

Metric system

SIR—There is a further problem to be considered in the controversy about ambiguities in metric notation, affecting the acquisition of mathematical concepts by school children.

In the days of Imperial measures, areas used to be denoted in units of square inches, square feet, etc. Such quantities were usually written in the form: "16 square inches" or "16 sq. ins". This was naturally read by the child as "sixteen square inches", and was quite unambiguous.

Nowadays it is common to denote areas in the metric system as follows: "16 cm^2" which is naturally read as "sixteen centimetres squared". A very understandable confusion then arises in a young mind between "16 centimetres squared", which is just acceptable as a way of expressing 16 cm^2, and "sixteen centimetres square" which can only mean 256 cm^2.

The meaning of "sixteen square centimetres" is thus obscured, and is not easy to clarify in verbal terms.

The fault arises, of course, from the linguistic confusion between "square" and "squared" which employs minimal coding to represent an important difference. However this confusion is not helped by a system of notation which itself confuses units and quantities.

Further anxieties about AIDS

AIDS has been a serious problem of public health since it was first recognized. The realization that it may affect the human nervous system gives a new twist. But the remedies are the same.

The letter from the Drs Fox on page 8 has plainly been written to scare, but it should be taken seriously for all that. Since AIDS (acquired immune deficiency syndrome) was first recognized, it has been seen as a serious threat to public health. It is intractable and infectious, although not especially so. What the Drs Fox (respectively a pathologist and a physician) are saying is that the threat is probably more serious than has been thought, now that it has been demonstrated that infection by the AIDS virus, HTLV-III or LAV, can damage the central nervous system. But it is too soon to know how much more serious.

While so much remains to be understood about the consequences of infection by the AIDS virus, it is not surprising that uncertainty abounds. But the wonder is that so much has been learned about AIDS and its causes in a mere four years.

The immune deficiency that marks out AIDS arises because of the depletion of the sub-class of T (for thymus) lymphocytes known as "helper" cells. Infected people produce characteristic antibodies, by means of which diagnostic tests have been developed and put into service. Their most immediate use is in the screening of blood for transfusions; it is too early to know how effective they will be.

Two lessons have emerged from the determination in the past year of the nucleotide sequence of several isolates of the virus. Viruses recovered from different sources differ — suggesting antigenic variability like that which makes the influenza virus variable — and the AIDS virus is less like HLTV-I (recovered from patients with apparently infectious adult T-cell leukaemia) than visna virus, responsible for a progressive (demyelinating) disease of the nervous system of sheep.

A great deal has also been learned about the nature of AIDS itself. That only some, perhaps 10 per cent or so, of those with HLTV-III antibodies succumb to one of the infections or other conditions that characterize the disease is not surprising. Other viruses may affect people subclinically, causing them little trouble but stimulating the production of antibodies which protect against further infection.

Much has also been learned about the mechanism of the spread of AIDS. Homosexuals, haemophiliacs given contaminated blood-clotting factor and syringe-using drug addicts are the groups chiefly at risk, but the disease has also been transmitted to heterosexual partners of homosexual men and by infected women to their children *in utero*. Blood-to-blood transmission is the surest route to infection. Little is known about the effectiveness of other methods of transmission, but the AIDS virus is plainly not particularly infectious. Even so, it is reasonable to expect that in due course the infection will spread through the general population in the narrow sense that the groups now most at risk will be less conspicuous. This is what seems to have happened in some parts of Central Africa.

It is a triumph that questions like these have been successfully answered in so short a time. Even so, there remain some curious puzzles. If, for example, the underlying defect in AIDS patients is immunosuppression, why should the rare skin cancer called Kaposi's sarcoma, believed by some to involve cytomegalovirus as a kind of co-carcinogen, be such a common sequel to infection by HTLV-III? Why not other kinds of cancer? And what is the status of those who carry antibodies against HTLV-III but show no overt AIDS? Are they patients in waiting, just lucky or is there an explanation of their apparent immunity?

This is the point from which the Drs Fox start. What, they ask, if those without overt AIDS who have been infected by the virus are at risk of succumbing instead to one of the neurological conditions associated with overt AIDS? What would happen if psychiatric hospitals were refilled with relatively young people suffering from conditions at present associated with old age, dementia for example? Could we shoulder the social burden? The question is chilling. Is it fair?

Over the past few months, there has been a trickle of articles in the clinical journals pointing to a neurological component of AIDS. From the outset, physicians have recognized what is vaguely called "AIDS-related encephalopathy" in some overt infections. The new development (see, for example, Ho *et al.* and Resnick *et al.*, both in *New. Engl. J. Med.*, **313**, 1493 & 1498; 1985) is the recognition that HTLV-III virus may infect brain tissue (promoting the formation of antibodies in the cerebrospinal fluid) and that it may be directly responsible for some of the damage done to the nervous systems of people with AIDS. More ominously, some of those in whose nervous tissue HTLV-III has been found are people without overt AIDS.

These investigations are still few and far between. Knowledge of the neurological complications of AIDS itself is only sketchy. As yet, there is no factual basis for an attempt to guess at the frequency with which virus reaches the brains of those who have merely been infected with the virus. But if the apparent similarity between HTLV-III and visna virus is sustained by further investigations, and because HTLV-III is a retrovirus that may become a part of the genome of somatic cells and nervous tissue in particular, there is a danger that AIDS infection may be hidden in the brains of human beings much as the herpes simplex virus (which causes "cold sores") may linger dormantly in the peripheral nervous system, bursting out only from time to time.

This is the background against which the Drs Fox have written their scary letter. There is a possibility that HTLV-III will lodge in infected people's brains, serving both as a cause of direct neurological damage and as a reservoir for the infection of others. Plainly there is an urgent need that this possibility should be explored, not least because virus in the brain may be less accessible to therapeutic drugs. Plainly, that will take time.

What, in the meantime, should be done? Reactions to the emergence of AIDS as a public health problem in industrialized communities has spanned the usual spectrum from panic to complacency. Many have responded with exaggerated fear to the notion that casual contact may infect them, while the primitive response of those who believe that Lot's wife met her deserved fate on the escape from Sodom and Gomorrah has been distasteful and unhelpful.

A strategy for containing AIDS can consist only of two components — some means of decelerating the spread of infection (which is a short-term measure) and, later, some means of preventing infection of those at risk. Infection by contaminated blood products should soon be halted. No doubt the fear of infection has already had an important influence on the behaviour of homosexuals, perhaps even drug addicts. But the benefits will emerge only slowly and the prospects for prophylaxis and cure are still distant. The recognition that there are probably neurological consequences of infection by HTLV-III makes a serious problem of public health still worse.

John Maddox

Immunology

Approaches to AIDS therapy

from David Klatzmann and Luc Montagnier

MUCH publicity has been given to the announcement by a group of French physicians of their treatment of acquired immune deficiency syndrome (AIDS) with cyclosporin A, an immunosuppressant. After four days of treatment with the drug, the T4 lymphocyte count of one patient rose from 4 to 250 cells per microlitre (900 ± 400 being the normal value), most of which seemed to be immature lymphocytes[1]. But it was later announced that whereas 10 patients with AIDS or the AIDS-related complex had shown similar initial improvements in T-lymphocyte counts, the original patient had died 15 days after treatment began. At first sight, it may well seem counterproductive to treat an immune deficiency disease with an immunosuppressant. There is some theoretical basis[2-4] for such treatment if AIDS is considered to be a virus-induced autoimmune disease but, because of the hazards of immunosuppressive treatment, the evidence for and against AIDS as an autoimmune disease needs to be carefully considered.

The most frequent clinical expression of AIDS is the occurrence of severe opportunistic infections, reflecting a profound defect of cellular immunity. Laboratory analysis demonstrates a broad spectrum of immune abnormalities[5], among which is a drastic reduction in the numbers of T4 lymphocytes in peripheral blood and secondary lymphoid organs as well as an impairment of their functions[6,7]. This may be accounted for by the biological properties of the AIDS virus, LAV[2] (also known as HTLV-III or ARV) which displays a selective tropism for normal T4 lymphocytes both *in vitro* and *in vivo*[8]. Intensive replication of the virus in cultured T4 lymphocytes is accompanied by a cytopathic effect which includes inhibition of cell growth, virus-induced fusion of the plasma membrane and, eventually, destruction of the cells[8].

It is unlikely, however, that AIDS is the result of a direct progressive destruction of T4 cells by the virus for at least two reasons. The first is that the replication and cytopathic effect of LAV can only be observed in activated T4 cells[2,9]. Indeed, LAV infection of resting T4 cells does not lead to viral replication or to expression of viral antigen on the cell surface, while stimulation by lectins or antigens of the same cells results in the production of viral particles, antigenic expression and the cytopathic effect. An equivalent phenomenon has been extensively documented for visna virus[10], the expression of which is associated with the activation of latently infected macrophages[11]. Visna virus is the prototype of the lentivirus family of retroviruses and comparison of LAV and visna virus nucleotide sequences strongly suggests that LAV is also a lentivirus. Indeed, comparison of protein and nucleotide sequences of various retroviruses generates phylogenetic trees demonstrating that not only LAV and visna but also caprine arthritis-encephalitis virus and equine infectious anaemia virus (the latter being antigenically related to LAV[12]) are members of a subfamily of retrovirus that diverged early from other retroviruses such as oncoviruses[3,13].

The second reason to doubt that the destruction of T4 cells by LAV is the cause of AIDS is that only a small proportion of these cells is infected by the virus. It is not clear why this is so because, by definition, all T4 cells carry T4 molecules on their surface and these molecules seem to act as the receptor by which LAV enters the cells[14,15]. And yet in purified T4-cell cultures, even at the peak of virus replication only 5–10 per cent of the cells express viral antigen and are subsequently lysed by the cytopathic effect[8]. Furthermore, only 10–20 per cent of clones derived from the CEM T4 cell line are susceptible to LAV infection, even though they all express the T4 molecule on their surface[16]. A similar picture emerges from studying patients: *in situ* hybridization with viral DNA probes indicates that less than 1 in 10,000 lymphocytes are replicating LAV at a given time[17] and the Southern blot hybridization technique, which can detect as little as one copy of viral DNA per cell, yields negative results on fresh peripheral blood lymphocytes of AIDS patients[18].

Taken together, these observations provide evidence against direct destruction of the T4-cell system by virus infection and replication. Therefore, one has to envisage alternative theories that explain the impairment in T4-cell number and function that characterizes AIDS. What could these be?

Immunosuppressive proteins

One possibility could be that LAV, like human T-cell leukaemia viruses I and II[19] as well as mouse and cat leukaemia viruses, possesses a protein in its envelope (p15E) that is able to induce immune depression of T-cell function. But no such protein seems to be produced by LAV. Various reports have suggested that sera of AIDS patients contain soluble factors that can suppress *in vitro* T-cell functions[20]. Such factors have not been characterized and their viral origin has not been proven but at least the observation that viral proteins are released during *in vitro* LAV production by lymphocytes[21] is consistent with the idea. The availability through genetic engineering of viral purified proteins should help in testing this hypothesis in the near future.

Autoimmune mechanisms

The role of viral infections in triggering autoimmune diseases is well documented. For instance, diabetes in mice can be caused by an immune destruction of Langerhans cells following their infection by viruses such as coxsackie strains[22]. In retroviral infections, such a mechanism has been invoked for the encephalitis induced by visna virus and the haemolysis induced by equine infectious anaemia virus. AIDS patients often display signs of autoimmune reactions that are probably secondary to cell destruction caused by various opportunistic infections, but a more specific autoimmune process may be triggered by the ability of LAV envelope proteins to bind to T4 molecules. Indeed, not only virions but also free LAV proteins released from LAV-producing lymphocytes may bind to T4 molecules on the surface of uninfected lymphocytes. This could explain the general disappearance of detectable T4 molecules on the surface of LAV-infected cultured T4 lymphocytes in which only 10 per cent of cells seem to express viral antigens.

Whether this also occurs *in vivo* is not known, but if it does, the result could be that non-infected lymphocytes become highly immunogenic because of their surface-bound T4 molecules. This could account for a general destruction of the T4-cell system by classical cellular and antibody-mediated cytotoxicity[4]. The whole pathophysiology of AIDS would then be the result of a situation in which the few LAV-infected cells in the resting state are invisible to the immune system because they do not express viral antigens. Each time these cells are stimulated, not only they but also many non-infected cells will be destroyed by the immune system because they have become coated by LAV proteins. Thus, the immune deficiency induced by LAV infection would be the result of an active autoimmune destruction of the T4 lymphocytes, probably enhanced by the repeated stimulation of the immune system by antigens or alloantigens.

Rational therapy

According to the pathophysiology of the disease, three therapeutic approaches to AIDS can be distinguished. The first is the development of drugs to destroy viral particles and infected cells, or at least stop the virus spreading. After *in vitro* screening, drugs such as HPA23, suramin and ribavirin have demonstrated antiviral activity and are now being tested in controlled clinical trials. Preliminary results indicate that LAV cannot be isolated from patients' lymphocytes during treatment but that the virus reappears at the end of treatment; moreover, the control of virus spreading is not associated with an immune or clinical improvement[23,24].

A second approach involves immune stimulation or reconstruction. Immunostimulators alone, even pure interleukin-2, seem to fail to reconstitute the immune system of AIDS patients. Interferon, which has both antiviral and immunostimulant effects, seems to be of value in the treatment only of Kaposi's sarcoma, which is often associated with AIDS. In any case, since cell activation probably contributes to virus spreading and T4 depletion, the use of such drugs in patients with minor symptoms of LAV infection may be dangerous in that it could accelerate progression of the disease unless antiviral drugs were used at the same time. Immune reconstitution by bone-marrow graft or leukocyte transfusion has been found not to work because the grafted cells are rapidly reinfected by the virus[25].

The third approach would be based on the view that AIDS is an autoimmune disease. This would suggest that immunosuppressive drugs, which can limit both cell stimulation and cytotoxic mechanisms, have a role in the treatment of AIDS. In that case, treatment would be designed first to control virus replications and then to 'tolerate' non-infected cells coated with viral proteins, in the way an allograft can be tolerated. Since there is still no firm basis for such a therapeutic approach, which is potentially dangerous, caution is required before clinical trials. While immunosuppressive treatment has been used in visna-infected animals with clinical improvement of early brain lesions without any adverse results[26], there are descriptions in the literature of patients who have died of fulminant *Pneumocyctis carinii* pneumonia after being treated with immunosuppressive drugs in ignorance that they were LAV-infected[27]. Even if cyclosporin A has some potential use in virus-induced autoimmune disease, its use in AIDS patients should await more experimental knowledge about its action on T cells, which may be highly complex[28].

Finally, because of the complexity of the pathophysiology of AIDS, only active and constant cooperation between biologists and clinicians will lead to an effective therapy, probably involving a combination of drugs and other treatments. ☐

Weather forecasting

Storm hunting with fractals

from A. Hollingsworth

MRS BEETON might well have observed that to make tiger soup, first catch your tiger. Tigers for a weather forecaster are vigorous storms that put life or property at risk. They occur on scales ranging from the tornado (~1 km) to mid-latitude cyclones (~2,500 km). Locating the whereabouts of a storm and estimating its ferocity are the first steps in making a useful forecast, but the surface meteorological network is very inhomogenous, with holes of many sizes where storms can lurk undetected.

On page 43 of this issue, Lovejoy *et al.* describe this problem in the language of fractal analysis. They give a definition of the dimension of an observing network, and argue that if the dimension of the network is lower than the dimension of the field being observed, many of the most energetic entities will never be detected. Many geophysical networks including the surface weather network are patchy in coverage and therefore lack dimensional resolution. Lovejoy *et al.* argue that long-term averages of geophysical fields derived from such dimensionally incomplete networks may be substantially biased: because of the inhomogeneity of the surface network, rare but vigorous events can be missed.

This suggests a bleak view of the feasibility of useful weather forecasting, a view which is belied by the fact that economically useful forecasts are routinely made out to perhaps 3 days in the tropics, 4 or 5 days in the southern hemisphere, and 6 or 7 days in the northern hemisphere extratropics. The success of the forecasts depends heavily on data sources other than the surface network as well as on sophisticated data-assimilation systems; ultimately success depends on the fact that scale separation is a meaningful concept for many practical purposes.

Data from polar orbiting and geostationary satellites, from the balloon network and from ships and aircraft provide the main basis for routine forecasting. The geostationary satellites, of which four are currently operational, provide multichannel measurements every half-hour over their field of view, which is roughly within 55′ of the nadir point at the equator (Fig.1). Cloud track winds can be derived from successive half-hourly scans in the visible and infrared. The satellites have a resolution of 1 km at nadir, and are invaluable for surveillance of tropical disturbances on all important scales. Two polar orbiting satellites provide radiometric soundings with good horizontal resolution four times a day, for most parts of the globe (Fig.2). Vertical structure in humidity and temperature can be derived from the soundings; in middle and high lati-

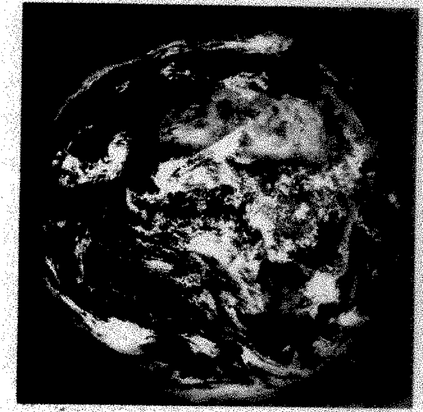

Fig. 1 Meteosat picture for 12.00 on 17 September 1985. The disturbance off the West African coast is the African wave that eventually developed into Hurricane Gloria. Cloud track winds can be estimated from successive half-hourly scans. The infrared channels enable one to estimate the height of the clouds. Pixel resolution at nadir corresponds to 1 km.

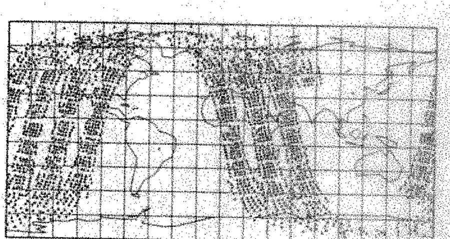

Fig. 2 Data coverage from a polar orbiter in a single six-hour period, covering about three orbits. A single orbiter can monitor every point on Earth twice a day.

tudes, the temperature soundings are valuable in inferring the winds.

The data from these diverse sources are integrated in a coherent view of atmospheric structure in space and time using four-dimensional data-assimilation methods. At the core of these techniques is a sophisticated global forecast model which provides rather accurate estimates of the expected state of the atmosphere, based on earlier observations. At any given time the observations are insufficient to determine the atmospheric structure.

Information from the forecast model is used in conjunction with the latest observations in a Bayesian estimation of the true state of the atmosphere; the forecast model is essential to resolve the underdeterminacy of the observations. There are many analogies between the methods used in this field and those used, for example, in computational vision (see Poggio, T., Torre, V. & Koch, C. *Nature* **317**, 314; 1985) or the applications of the Kalman–Bucy filter in control theory (see *Data Assimilation Methods* eds Bengtsson, L., Ghil, M. & Kallen, E., 330; Springer, 1981).

Global weather forecast models solve a version of the Navier–Stokes equations for fluid flow on a grid which has a horizontal resolution of about 150 km and a vertical resolution of 1–2 km. Some important weather cannot be resolved on such a grid. The fact that one can nevertheless make useful forecasts suggests that the simplification of treating the atmosphere as smoothly varying on the smallest resolved scales is not a serious error. Statistical methods can, if necessary, be used to interpret the forecast in such a way as to recover useful local detail. ☐

Immunoglobulin genes

Inversion for gene construction

from David Baltimore

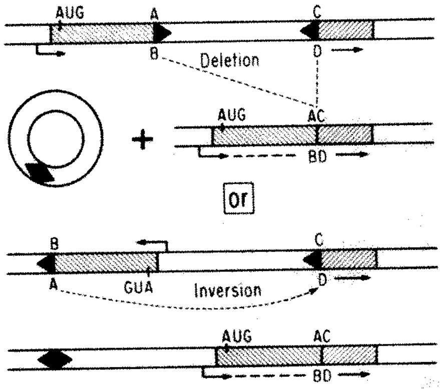
JOINING of immunoglobulin genes as an event of immunodifferentiation is not unique in the biological world. Recombination of DNA molecules is commonplace and serves many functions, including meiotic recombination, post-replicative repair, phase variation in *Salmonella* bacteria and the generation of transcribable surface antigen genes in trypanosomes. Although DNA recombination frequently occurs, somatic rearrangement of gene fragments to produce functional genes is at present known to be used only by the immune system. This specificity implies that the rearrangement process should be active only in particular cells and be targeted only to well-defined DNA segments. On page 28 of this issue Malissen *et al.*[1] have extended our understanding of the rearrangement process by their analysis of the T-cell receptor gene complex.

The nature of the enzymes involved in the immunoglobulin gene rearrangement process, their control and their targeting specificity remain mysterious — we are still trying to understand the ground rules. One of the more obscure aspects is the relative placement and orientation of the gene fragments to be recombined to produce the immunoglobulin molecule. Although textbooks and the diagramatic slides shown by many immunologists blithely display strings of variable (*V*), diversity (*D*) and joining (*J*) segments, the only situation where a complete physical linkage has been achieved for all the elements of an immunoglobulin gene-segment joining system is with chicken lambda genes[2]. For all mammalian systems, the relative positions and orientations of the elements to be joined are incompletely established. Various arguments give a strong indication of the organization and orientation of the immunoglobulin heavy-chain gene segments[3,4], but the situation for the kappa light-chain genes is uncertain. The joining of kappa-chain gene segments involves a recombination between one of many hundreds of *V* segments with one of four *J* segments.

Although the *V* and *J* segments have not been physically linked in recombinant DNA clones, Lewis *et al.* in 1982 proposed that at least some of the kappa *V* regions occur in the DNA chain in the opposite transcriptional orientation to the *J* segments[5]. This proposal was based on the observation that in certain cells that have productively rearranged their DNA, segments of DNA remain that should have been deleted if both *V* and *J* were found in the same orientation[5-7]. If a *V* segment were in the opposite orientation to a *J* segment, joining the two elements would have to invert the intervening DNA rather than deleting it. Such an inversion would not remove any large segments of DNA from the cell but would simply reconfigure the existing DNA. This proposal met with much disbelief largely, I believe, because the DNA gymnastics involved seemed formidable although, in fact, they are quite ordinary (see the figure).

A decision about whether inversional joining is a mechanism of rearrangement was approached in two further papers by Lewis *et al.*, who used an artificial DNA construct with inverted *V* and *J* segments that would rearrange after integration into certain cells[8,9]. This work showed that inversional joining is a feasible mechanism, but left open the question of whether it actually occurs in normal B-cell maturation. Two indirect pieces of data argued for inversional joining[10,11], but both involved abnormal events. The direct demonstration of inversional joining in the kappa gene of a plasmacytoma was made by Feddersen and Van Ness[12], who found that they could recover both products of a natural joint and showed that the two had to arise by inversional joining. This directly implied that some *V* regions are in opposite orientation to the *J* regions.

Malissen *et al.* have now extended the analysis to the *V* regions of the T-cell receptor gene complex. Here they have uncovered a most surprising situation (one that could as easily have been true of kappa light-chain genes and may yet turn out to be). They have shown that at least one *V* segment is downstream of the constant (*C*) regions. In all previously characterized systems of immunoglobulin-related genes, the *V* segments have been thought to be upstream of the other segments. For immunoglobulin heavy-chain genes, joining is accompanied by deletion of the intervening DNA[3] and this requires that the



The difference between deletional and inversional joining. The difference is solely in topological orientation of the two participating pieces of DNA. The units to be joined (the *V* and *J* units shown here) are identical but in one case they are located in the DNA in the same transcriptional orientation and in the other in opposite orientation. The biochemistry of joining is identical in both: the same sequences are joined to one another. This can be seen by following the locations of the hypothetical sequences A, B, C and D. In both cases of joining, A is joined to C and B is joined to D. The consequences of deletional and inversional joining are quite different. In the first, a segment of DNA containing the joining signals is released as a circle and discarded from the cell. In the second, no segment of DNA is lost from the cell but the inversion causes the back-to-back apposition of the joining signals. ↳, Site of initiation of transcription with direction indicated; AUG, codon in *V* region that initiates translation; ▶, signal encoded in the DNA that specifies a site for joining (a conserved heptamer and nonamer).

V regions be upstream of the *C* regions (if they were downstream, the *C* region itself would become part of the deleted DNA).

For a *V* region to be downstream of the *C* region, topological considerations dictate that the *V* region must be in opposite transcriptional orientation to the *C* region. Malissen *et al.* were able to verify this because the *V* and *C* regions are near enough to each other to be physically linked in cloned DNA. The structure that they uncovered, in fact, implies that the joined segment in the T-cell clone arose by an initial deletional join of an upstream *D* segment to a *J* segment followed by a *V*-to-*D* – *J* inversional join in the downstream direction.

It should be emphasized that all of the DNA mechanics that have been found to underlie T-cell receptor gene rearrangement are congruent to the events of immunoglobulin gene rearrangement. The DNA signals thought to direct the rearrangement process are indistinguishable in the two systems. Malissen *et al.*[1] reinforce this perspective by showing that *D*-to-*J* rearrangement precedes *V*-to-*D* – *J* rearrangement as found for immunoglobulin heavy chains. They also note that the joined genes have lost potential coding nucleotides found near the joining signals in the germline DNA elements and that new nucleotides (constituting an *N* region) are found between the joined *V* and *D* segments. The only surprise is that the reciprocal joint formed during the recombination retains three nucleotides between the heptamers. In all cases of immunoglobulin gene joining yet studied, the heptamers are joined back-to-back with no intervening nucleotides (in one case a join with one nucleotide missing was found; ref. 9).

With this demonstration of inversional joining of a T-cell receptor *V* gene segment, most of what we want to know about the topology of joining is available. All we now need is to understand the sequence requirements for joining; then we can turn to enzymology, a task already begun in many laboratories but with little reported success. □

PHYSICS AT JOHNS HOPKINS

The large and well appointed laboratories recently erected by the Trustees of the Johns Hopkins University for the Chemical and Biological Departments have by contrast made the more evident the needs of the Physical Department, which has been obliged to occupy temporarily parts of four different buildings for a physical laboratory. The new laboratory is to be a handsome building of red brick, trimmed with brown sandstone, and will occupy a fine site about a block from the other University buildings, on the corner of a quiet little street midway between the more important streets, which carry the bulk of the traffic. It will therefore be as free from disturbance from the earth-vibrations as could be expected in a city. The building will be 115 feet long by 70 feet broad and will have four stories besides the basement. In the centre of the building, and below the basement, are several vaults for instruments requiring to be used at constant temperature, also a fireproof vault for storage. In these vaults will be placed Prof. Rowland's dividing-engine, by which the diffraction-gratings are ruled, and the Rogers-Bond comparator, which has recently become the property of the University. There will be a tower on the south-east corner which will be provided with telescope and dome, and will be a convenient observatory when great steadiness in the instruments is not required.

Plate tectonics

Global thermal histories

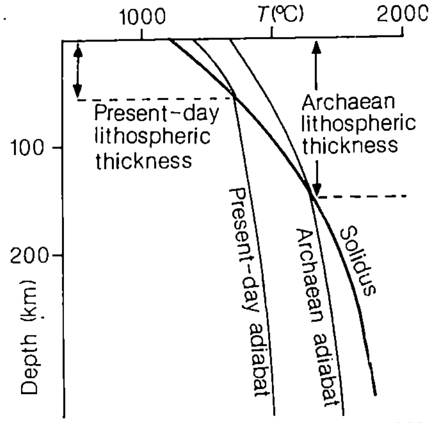
from Mike Bickle

Tectonic geology is a manifestation of the thermal evolution of the interior of the Earth. Surprisingly, models for this thermal evolution have proved difficult to reconcile with a geological record that extends over three-quarters of the history of the Earth. The relatively low crustal thermal gradients recorded in the earliest rocks are incompatible with the higher gradients predicted by convection models that incorporate the higher radiogenic heat production that must have then prevailed. After re-examining this problem, F.M. Richter (*Earth planet. Sci. Lett.* **73**, 350; 1985) concludes that low continental thermal gradients could only have been maintained in the Archaean if the continental lithosphere was stabilized by chemical means (that is, was less dense), rather than being a simple thermal boundary layer as seems appropriate for much of the present-day lithosphere. The concept of a chemically stabilized lithosphere is not new (see, for example Jordan, T.H. *Nature* **274**, 544; 1978) but it now seems that such stabilization was of greater importance in the past and may have had a profound effect on the evolution and preservation of ancient continental crust.

Models for global thermal evolution allow calculation of the temperature dependence of heat loss for a spherical, layered and convecting Earth. To be successful, a model must not only yield a plausible range of present-day interior temperatures (given an appropriate initial state), but must also account for the higher radiogenic heat production and loss of initial heat formation that must have occurred in the past. Successful models achieve this by generating internal temperatures higher than at present and thinner boundary layers with steeper thermal gradients.

Good evidence for higher internal temperatures is provided by komatiitic lavas, which are restricted to the Archaean and were erupted at temperatures about 200°C higher than any recent lavas. However, the geological evidence from metamorphic rocks, crustal thickness and sedimentary basin subsidence indicates that the range of crustal thermal gradients in the Archaean may not have differed significantly from the range of modern continental thermal gradients. This inference is strongly supported by the demonstration of Archaean ages for diamonds (Richardson, S.H. *et al. Nature* **310**, 198; 1984). The diamonds must have been preserved since roughly 3,200 Myr ago at depths greater than 150 km in continental lithosphere of at least similar thickness to present day continental lithosphere.

The problem addressed by Richter is how to allow higher interior temperatures without affecting that part of the boundary layer under the continents. Previous solutions have noted that heat is lost from the Earth's interior by two mechanisms: an unsteady small-scale convection of sinking and rising jets transporting heat to the base of the lithosphere through which it is subsequently lost by conduction; and larger scale recirculation of the whole lithosphere in oceanic regions, that is, plate tectonics. The driving and resisting forces involved in the second mechanism are difficult to quantify and there has been a temptation to assume that plate tectonics can transport any necessary extra heat. Richter has developed regional models to try to account for heat lost by both mechanisms as a function of internal temperatures. He looks particularly at the interdependence of the mechanisms. All his models with thermal boundary-layer definitions for the lithosphere result in boundary-layer thermal gradients that in-



Depth–temperature plot for the upper 200 km of the Earth, showing the intersection of the present-day and supposed Archaean temperature profiles with the mantle solidus (the locus of the onset of melting). Because of the increased depth of initiation of melting in the Archaean, the depleted lithosphere would have been thicker than today.

crease at a rate faster than the increase in heat production. This is because the effectiveness of plate-tectonic heat loss decreases as temperatures increase and plate thicknesses decrease. The only viable resolution of this problem is that the continental lithosphere is stabilized chemically rather than thermally.

How robust is this conclusion? All convection calculations involve a series of assumptions. U.R. Christensen (*J. geophys. Res.* **90**, 2995; 1985) has performed numerical calculations of convection in a fluid with a temperature-sensitive viscosity and raised some important questions about the validity of the parameterized calculations used by Richter. Such calculations estimate the temperature dependence of heat loss by comparing numerical convection models run at various newtonian viscosities, but with constant viscosity in each model. Christensen's experiments with viscosity as a function of temperature indicate that heat flux is less sensitive to temperature than previously thought. This is because the cooler higher-viscosity upper boundary layer controls convection rates; hence the heat flux is related to some temperature in the upper boundary layer rather than the substantially higher interior temperature used as a scaling factor in the parameterized calculations. Christensen's calculations indicate how much has to be learnt about convection in variable viscosity and non-newtonian fluids appropriate to the Earth's mantle.

Nevertheless, such complexities seem unlikely to affect Richter's basic conclusions. Heat flux from the Earth is necessarily fixed at a rate sufficient to allow the Earth to cool to its present state from initial temperatures high enough to allow substantial but incomplete outgassing. In addition, Richter's calculations span a range of viscosity–temperature relationships including the limiting case of viscosity independent of temperature. Interior temperatures are less well constrained by parameterized models, but no model based on the lithosphere as a simple thermal boundary layer allows global heat to rise without increased heat input into the continental lithosphere.

The heat loss considerations allow some interesting speculations about Archaean tectonics, which are important because they lead to possible tests of the hypothesis of a chemically depleted continental lithosphere. Increased mantle temperatures cause melting to be initiated at greater depths. For example, at 1,600°C, appropriate to the Archaean mantle, melting might be initiated at about 150 km under mid-ocean ridges compared with depths of roughly 60 km for modern mantle (at approximately 1,350°C). This could yield a depleted lithosphere 150 km thick with 25 km of oceanic crust (see figure). The former might be converted to continental lithosphere by accretion of island arcs. Stabilization of the lithosphere by depletion to the depth at which melting is initiated seems essential to preserve Archaean crust from an alternative tectonic mode postulated by Richter. If convection penetrated into regions of partial melt below continental lithosphere the overlying crust would be continuously buried beneath copious volcanicity. This would lead to subsidence, stablization of a cool dynamically thickened thermal boundary layer and continous recycling of the volcanic material down into the underlying mantle. Such a process is incompatible with preservation of Archaean crust and if it operated must have been restricted to a pre-Archaean period or perhaps to those areas of Archaean crust not preserved.

The postulate of a thick chemically depleted continental lithosphere is testable. Isotope data, including those yielding the age of garnet inclusions in diamond, can demonstrate the antiquity of periodotite xenoliths (such as are found in kimberlite pipes) putatively derived from the continental lithosphere. Their chemistry can indicate the degree of chemical depletion. A critical point yet to be resolved is whether the density decrease due to chemical changes is adequate to stabilize the lithosphere against the thermally induced density increase which limits the thickness of modern oceanic lithosphere (Houseman, G. & McKenzie, D.P. *Geophys. J.R. astr. Soc.* **68**, 133; 1982). ☐

Protein structure

Polar pocket with nonpolar lining

from David J. Cowley

CLASSICAL crystallographic studies of the globular protein myoglobin (Kendrew, J.C. *et al. Nature* **185**, 422; 1960) showed the oxygen-carrying plate-like haem group to be embedded in a pocket that is lined largely with nonpolar amino acids. But on page 70 of this issue R.B. MacGregor and G. Weber report optical spectroscopy studies with a new fluorescent probe, which indicate that the haem cleft has a polar interior.

Like the commonly used probe amino-naphthalene sulphonate, the new probe DANCA* has spectroscopic properties that reflect the polarity of its environment. But it has the advantage that the dipole moment on electronic excitation changes markedly in strength but not in direction. Such changes, detected spectroscopically and compared with the probe's optical properties in a series of homogenous solutions of defined polarity, allow the ready estimation of the local polarity of a biological macromolecule enveloping the rigid probe chromophore.

DANCA has a high affinity (dissociation constant 1.2×10^{-5} M at 24°C) for apomyoglobin because its carboxylic acid group mimicks that of haem itself. PRODAN*, which has neither the high affinity for apomyoglobin nor the carboxylate group of DANCA, nevertheless has nearly identical absorption and fluorescent properties and can therefore be used for calibration purposes for solvents in which DANCA is insoluble.

Bound DANCA can be displaced stoichiometrically from apomyoglobin by one equivalent of haemin, showing that the probe is not loosely associated at a variety of sites but is located only in the protein pocket. On binding of DANCA to apomyoglobin in aqueous buffer at *p*H 6.0, the fluorescent emission intensity increases fourfold and the emission band shifts to higher energy. The emission spectrum is similar to that of DANCA in the very highly polar solvent *NN*-dimethylformamide at 20°C or in glycerol at −40°C. It is the gross redshift of the emission band relative to PRODAN in nonpolar cyclohexane solvent that reveals the high effective polarity of the interior of the myoglobin pocket.

The apparent paradox of a pocket lined with nonpolar amino acids and yet with a high effective polarity is resolved if the amide dipoles (C=O...H–N) disposed around the rim of the segments of alpha

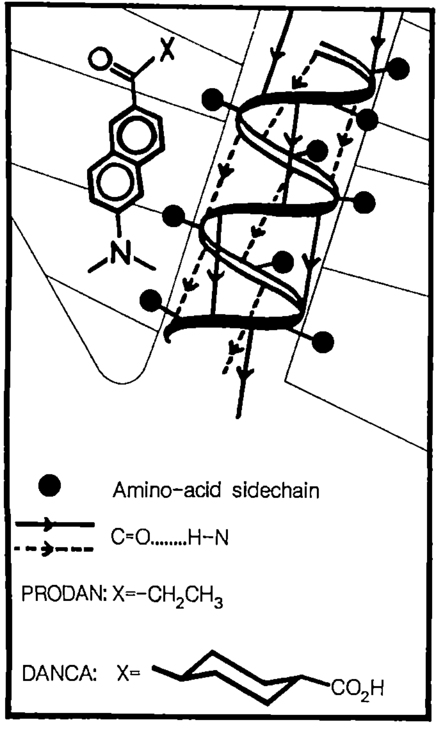
---

*DANCA is 2′-(*N*,*N*-dimethyl)amino-6′-naphthoyl-4-*trans*-cyclohexanoic acid; PRODAN is 6-propionyl 2-(*N*,*N*-dimethyl)aminonaphthalene.

helix forming the haem pocket can exert substantial electric fields inside the pocket despite the attenuation by the insulating lining of hydrocarbon side chains (see figure). Calculations confirm the feasibility of this explanation, which may apply to many enzyme interiors.

To infer environmental polarity from fluorescence band positions requires that the surrounding medium has had the opportunity to undergo a full adjustment to the excited chromophore before the latter emits light. Otherwise the emission spectrum shifts to longer wavelengths as longer wavelengths of light are used to excite selectively more stabilized solvated chromophores. This 'red edge effect' is observed for PRODAN in glycerol at −42°C but is absent above 1°C. Since 'solvent' relaxation must be complete, dependence of the emission of DANCA-myoglobin on the wavelength of excitation at room temperature is attributed to a heterogeneity of probe orientations within the haem pocket. Haem itself binds in two distinct orientations. The reported steady-state fluorescence studies provide limited information. Time-resolved spectra and fluorescence anisotropy decay data would enable the rotational constraints on the bound probe and the exchange rates between probe configurations to be evaluated.

An additional redshift of fluorescence, above the expected solvent relaxation shift, incipient at −35°C and almost fully developed at 4°C, is intriguing. Despite the claimed merits of DANCA as a probe of well-defined geometry and electronic nature, the initial excited state may transform to a more polar, lower-energy excited state by twisting about the dimethylamino-naphthalene bond, with a likelihood that depends on the polarity and viscosity of the constraining medium. Such processes have been documented for many intramolecular charge-transfer systems analogous to DANCA, the classic example being *p*-*N*,*N*-dimethylaminobenzonitrile (Kosower, E.M. *Acc. Chem. Res*, **15**, 259; 1982 and Grabowski, Z.R. *et al. Nouv. J. Chim.* **3**, 443; 1979). If this were to be the case the 'environment polarity' would be overestimated. Notwithstanding, the high polarity of the myoglobin haem pocket is real.



The haem cleft of apomyoglobin

MacGregor and Weber calculate electrostatic interaction energies of a monopole charge within a square grid of locations in the haem plane, together with the partial charges of nitrogen and oxygen centres of the peptide backbone in the known crystallographic positions of deoxymyoglobin, on the assumption that the intervening nonpolar sidechains form a dielectric of relative permitivity 3. Several orientations of the probe molecule, represented by a pair of opposite charges 0.84 nm apart on the grid, were found to be capable of producing spectral shifts in excess of the observed shifts of ~1,000 cm^{-1}.

On the basis of the often minor changes in acid dissociation constants of protic groups in water and inside certain proteins, it has been deduced that many protein cavities have a high effective polarity despite the lining of 'nonpolar amino-acid residues' (Warshel, A. *Proc. natn. Acad Sci. U.S.A.* **81**, 4785; 1984). These deductions are corroborated by the calculations and optical evidence of MacGregor and Weber. ☐

Glynn Isaac 1937–1985

GLYNN ISAAC died in a hospital in Japan on 5 October after a brave fight against a vicious, and as yet unidentified, infectious illness. Although 'officially' an archaeologist, he drew no boundaries between disciplines in his pursuit of evidence about the origins and early stages of human behaviour. His field contributions are important enough in their own right, but Isaac will mainly be remembered for his eclectic use of evidence and for his passionate insistence that the hypothetico-deductive method can, and should, be applied to problems of prehistory.

Glynn Isaac's introduction to archaeology began as a schoolboy and continued as a student in Cape Town, and came from A.J. Goodwin and Monica Wilson. His mentors at Cambridge were Graham Clark and the late Charles McBurney. In 1961 he accepted a research post with Louis Leakey in Kenya which was the beginning of his professional association with African prehistory. Louis and Mary Leakey had investigated the site of Olorgesailie between 1942 and 1954 and, with typical generosity and perspicacity, Leakey gave Isaac the responsibility of further excavating and analysing the site. Isaac's monograph on Olorgesailie is a classic of its kind, and contains clear evidence of his sensitivity to the confounding problems that the geological context can bring to the interpretation of archaeological sites.

Field work in Nakuru and in the Natron Basin followed and it was at Natron, at Penini, that Isaac began his association with Richard Leakey. In 1969, Leakey invited Isaac to investigate the archaeological evidence which had then been recently discovered at the KBS site, at what was then East Rudolph, now Koobi Fora, in northern Kenya. However, Issac's contribution to the work at Koobi Fora was much wider, for he joined Leakey as co-director of the Koobi Fora research project and was instrumental in the development of nearly all aspects of the research that flowed from that area. His broad training in zoology and geology was crucial for this task. His strength as a scientist was most evident at the time when there was a conflict between the isotope and palaeontological evidence for the age of the KBS tuff. Isaac was determined to see, and was instrumental in achieving, the reassessment of the evidence. The apparent resolution of this problem proved to be the stimulus to important geochemical research which has resulted in more precise and accurate correlations of ash layers at four of the major East African sites.

Isaac was an inveterate hypothesis maker. His hypotheses about early hominid land use, behaviour and subsistence were mostly based on evidence that he and his collaborators had painstakingly recovered at Koobi Fora and elsewhere. The diverse and pertinent projects undertaken by his students, from studies of food availability to contemporary hunter-gatherers to the factors which disturb contemporary archaeological sites, speak for his willingness to put his own ideas to the test.

Isaac loved Africa and its people and he, more than any other, saw the need and the obligation to involve Africans in prehistory research. Prehistory is a field not usually noted for the humility of its practitioners but Isaac stood out as being wholly without self interest. His enthusiasms and influence spread far, and his impact on palaeontology, dating and on the conduct of anthropological field and laboratory research, as well as prehistoric archaeology, were more profound than I suspect we presently realize.

Endangered species

The fate of the California condor

from David S. Wilcove and Robert M. May

CALIFORNIA condors (*Gymnogyps californianus*) have soared over the foothills and valleys of the western United States since the Pleistocene. Whether they will survive the twentieth century is another matter. Recent counts indicate that only six condors remain in the wild, with another 21 in captivity. The future of North America's largest bird rests with these 27 individuals.

The heyday of the condor is long past. Fossil remains indicate they once occurred from British Columbia in Canada to the southern extent of Baja California in Mexico, and eastwards across the southern United States to Florida. The rich Pleistocene mammal fauna as revealed in the Rancho LaBrea tarpits must have provided abundant food (carrion) and one can imagine the condors squabbling over the carcass of a mammoth. At that time, there were a number of giant scavenging birds in North America, of which the condor is the only surviving species.

Within historical memory, condors still occurred all along the Pacific coast of North America, yet almost as far back as the records go, they have been in decline. By 1850 they had almost disappeared north of California; by 1940 there were none left in Baja California. For most of the past 50 years, they have occupied a U-shaped area of about 45,000 km^2 from Santa Barbara south along the coastal range to San Jose and along the western foothills of the Sierra Nevadas to southern Madera county.

The first condor census, published in 1953 (ref. 1), gave an estimate of 60 birds, but this was obtained without marking individuals and is now believed to have been far too low[2]. By 1978, only 25 – 35 condors were thought to remain in the wild. Four years later, some of the wild birds were brought into captivity and eggs were collected for captive hatching. The captive population has grown steadily but so far only by supplementary wild eggs and birds, because it will be several years before most of the captive birds are old enough to breed. The wild population, meanwhile, had dropped to 15 by October 1984 and another six birds had disappeared by May 1985, when three of the survivors were brought into captivity. All the wild birds today are radio-collared, which should allow biologists to monitor them closely.

Many explanations have been offered for the decline of the condor. In the vivid but teleological language of some earlier ecologists, it was termed a senile species: a bird whose low reproductive rate (one offspring every two years), lengthy adolescence (six or more years) and vast home range ill-suit it for life in modern-day southern California. The demise of the condor may, therefore, be simply a protracted coda to the larger extinctions that occurred about 10,000 years ago as recorded at Rancho LaBrea. Although there is some truth in this, for conservation purposes it is more useful to focus on the specific environmental problems that plague the condor, including molestation by humans, food shortages, environmental pollution and habitat destruction.

At the turn of the century, when a condor egg was worth as much as $300, many of the nests were robbed. Federal protection has eliminated this threat but it has not prevented the occasional loss of adult birds to hunters. There is debate about the extent to which such vandalism is responsible for recent losses.

End of the line? (Frank Lane picture agency).

Some have suggested that the extinction of the Pleistocene megafauna resulted in a food shortage for the condor, but there were large herds of antelope and elk in the San Joaquin and Sacramento Valleys until the mid-nineteenth century. The expansion of ranching in this region provided the condors with abundant livestock, chiefly cattle, sheep and horses[3], although the switch to agriculture in the early 1900s probably did reduce their food supply. A programme providing food supplements was started in 1971 (ref. 4).

A far more serious problem has been contamination of the food supply. Condors ingest lead when they dine on animals that have been shot by hunters[5]; at least two birds have died in the past three years from lead poisoning and lead levels in the remaining wild condors are alarmingly high. Levels of DDE in tissue samples from wild condors are high enough to cause reproductive problems, assuming that condors are as sensitive as most birds of prey to DDE[5]. Eggshells of California condors from 1964 – 1969 were 33 per cent thinner than in the pre-DDT era[6].

As the condors live in one of the nation's fastest growing areas, not surprisingly their habitat is under assault. Oil production and urbanization are continually extending into the grasslands where the birds forage, and mining and timber interests would like greater access to the mountainous regions where the birds roost and nest.

The US Department of the Interior must weigh all of these factors when deciding what to do with the remaining condors. Some scientists have recommended that the remaining wild birds be brought into captivity for safe-keeping. Their argument, which seems unanswerable to us, is that a programme of breeding captive birds is the only thing that can save the species, but others think that removing wild birds will eliminate any chances for re-introducing captive-bred individuals to the wild. Without older birds to show them where to roost, nest and forage, new recruits have little chance of surviving.

This argument epitomizes the choice that is likely to face us increasingly often, as more species are driven to the brink by human population expansion: do we settle for preserving specimens of each species in some form of zoo or do we strive, possibly hopelessly, to preserve the ecological entity with its full panoply of behaviour in the wild? In the case of the condor, some urge that a few be left wild, because it may be politically impossible to fend off the assaults on their habitat if there are no wild birds left[7]. The most recent agreement hammered out between the State of California and the Department of the Interior proposes the capture of three of the six remaining wild condors with simultaneous release of three captive birds, but the agreement is contingent on the department purchasing a 14,000-acre tract of land needed for condor conservation, and will probably collapse if any more wild birds die in the next four months.

California condors were around long before the first humans colonized the New World. It may be a measure of the success of our own species that we have all but eliminated the condor. Another measure will be whether we can now save it. ☐

Trialkyl lead in rain in the Black Forest

SIR—We have recently suggested that high concentrations of trialkyl lead, R$_3$Pb$^+$, as detected, for example, in rainwater samples from the Black Forest, may be harmful to the forests of Central Europe[1]. The theory has been seriously questioned by M.H. Unsworth and R.M. Harrison[2]. We wish to provide some new and supplementary data, which we believe can help to remove their doubts.

The most serious questions posed by the authors concerned the bioassay used for quantitation of R$_3$Pb$^+$. In continuing our study for several months of this year on behalf of the government of Baden-Württemberg, two independent methods have been employed for the determination of R$_3$Pb$^+$ in rain water. In addition to the tubulin assay, all samples were submitted to a chemical separation procedure[3] which was also used for the determination of some of the concentration values cited by Unsworth and Harrison. The results of both assays were the same within the limits of experimental error. Again, four of the samples collected at two locations in the Black Forest had trialkyl lead concentrations higher than 0.2 μM.

Unsworth and Harrison were concerned about the likelihood of the occurrence of such high concentrations of R$_3$Pb$^+$ in rain. The concentrations are indeed 100–1,000 times higher than those reported by others. So far, however, analytical data on trialkyl lead in rain are scarce. The few data known are from locations with a typical sea climate, which may not be comparable to locations on the Continent. Moreover, the occurrence of trialkyl-lead-polluted rain seems to be confined to small areas, as shown by the analytical results obtained from one of our sampling stations which, although located only 100 km east of the Feldberg, has never given R$_3$Pb$^+$ values above the limit of detection. Sampling at this site alone would have led to different conclusions. Finally, the Antwerp data mentioned by Unsworth and Harrison were one-sample measurements, and therefore statistically insignificant. In 1984, it took us 4 months of uninterrupted observation before we recorded a single toxic event.

Unsworth and Harrison argue that the low concentrations of R$_3$Pb$^+$ in the atmosphere cannot account for the high concentrations of R$_3$Pb$^+$ in rain. For the undegraded compound R$_4$Pb, Harrison and coworkers[4] reported atmospheric concentrations at rural sites of up to 230 ng m^{-3}. After degradation, the distribution of R$_3$PbX can be expected to remain unchanged, at least for some period of time. However, values of R$_3$PbX were reported to be as low as 2 ng m^{-3}. So where is the rest? The loss is most easily explained by the high instability of salts when dispersed in air. They may be captured by polar media, such as surfaces of particulate matter, and would therefore be analysed together with the inorganic lead. Indeed, in most of the studies of atmospheric lead pollution, the term "inorganic lead" stands for the lead fraction removed by filters. R$_3$PbX could be washed off the surface of such particles, on contact with rain or fog. In our example, 230 ng of R$_3$PbX would be dissolved in about 10 ml (10 g m^{-3} is the typical atmospheric humidity in Europe). The resulting concentration would be about 10^{-7}M, which is within the range of R$_3$PbX found in the Black Forest. This value does not consider the R$_3$PbX that may be taken up by rain on its way from clouds to the surface.

Fortunately, we do not disagree on controversial theories but on a finding that can be examined experimentally. Therefore, we suggest that further discussion should be postponed until our results have been confirmed by others. Twin samples were taken of most of the rainwater samples collected in 1985 in the Black Forest. They are waiting to be analysed.

An anniversary for the lipid bilayer

SIR—The year 1985 marked the sixtieth anniversary of the proposal by Gorter and Grendel[1] that biological membranes consist of a double layer of lipid molecules, as appropriately mentioned by Bretscher[2]. In 1925 E. Gorter, a pediatrician with a strong interest in chemical pathology, and F. Grendel, a chemist in the laboratory of the University Children's Hospital at Leiden, The Netherlands, derived their cell membrane model from observations made with rather simple experimental techniques. The lipid extracted with acetone from a known amount of erythrocytes was spread as a monolayer on a water surface. The ratio of monolayer lipid area to total erythrocyte surface turned out to be close to 2: 1 for red blood cells from different mammalian species. Thus the investigators concluded with the suggestion that in the cell membrane of erythrocytes sufficient lipid is present for constituting a molecular bilayer. The structural model is the more remarkable because it was derived without any modern instrumental method such as infrared spectrometry, gas chromatography or electron spin resonance. Already 10 years ago, the Gorter-Grendel model was considered by Bretscher and Raff[3] a major breakthrough in cell biology, comparable to that of the double DNA helix. In 1934 Danielli and Davson[4] improved on the model by allowing for proteins to be additional components of plasma membranes. The fluid mosaic model proposed in 1972 by Singer and Nicolson[5], viewing functional biological membranes as bidimensional solutions of integral proteins in a liquid phospholipid matrix, remains the current basis for experimental work.

In 1966, Bar *et al.*[6] repeated the Gorter-Grendel experiments and discovered two major errors. First, acetone treatment extracts membrane lipids, and cholesterol in particular, incompletely. Second, more refined measurements of the surface area of the human erythrocyte yield the value of 145 ± 8 μm^2 instead of 99 μm^2, the value used in 1925. The Dutch investigators had in fact made two mutually compensating errors of about 40%.

We are proud that in 1935 Dr E. Gorter, at that time chairman of the pediatrics department at Leiden, accepted an invitation from Ghent State University to come and found the first university children's hospital in Flanders, Belgium. The strong interaction between pediatric observation and biochemical research, kindled by Professor Gorter, and promoted continually by his pupil and successor, Professor Hooft, who died in 1980, remedied effectively the developmental delay of pediatrics in Belgium. We owe much to Evert Gorter, who was once called: 'The best chemist among all pediatricians and the best pediatrician among all chemists.'

Scientific Correspondence

Scientific Correspondence is intended to provide a forum in which readers may raise points of a rather technical character which are not provoked by articles or letters previously published (where the Matters Arising section remains appropriate).

X chromosomes and dosage compensation

Sir—D.A. Smith (*Nature* **315**, 103; 1985) uses the term "dosage compensation" to mean that effect on the rate of transcription of X-linked genes in the male which enables it to survive the lack of one X chromosome; X inactivation in the female is, then, a further compensatory step to enable *it* to get over the problem of overactive X-linked genes. By suggesting that evolution could have somehow "resolved" the situation arising from aneuploidy for an entire X chromosome in the mammalian male, G.P. Maroni (*Nature* **317**, 22; 1985) asks whether the inferences drawn by Smith are valid. Purely in terms of the physiology of gene action, precisely what evolution had to "resolve" is not clear: in the course of their extensive analysis of the problem of dominance, Kacser and Burns[1] have shown that — special cases apart — metabolic fluxes are extremely insensititve to whether an enzyme is represented by one structural gene or two.

I wish to draw attention to a point that usually is not taken into account. Sex chromosomes are expected to include one or more sex-determining genes. If the mammalian X chromosome indeed contains genes determining primary sex, what such genes might require is not dosage compensation but full expression, or even exaggeration, of the difference in dosage between XX and XY genotypes. Thus it can be argued that dosage compensation (in the usual phenotypic sense) is unlikely to be the primary reason for X inactivation. Is it possible that X inactivation has a function more vital than dosage compensation? I have suggested that sex determination may be such a function[2]. The observed dosage compensation of *G6PD*, *HPRT*, *PGK* and such other X-linked housekeeping genes would then be, in the evolutionary sense used by Maynard Smith[3], an effect of X inactivation, not its function. This model requires that a distinction be made between dosage compensation at the level of the phenotype and that which might render the effective copy number of particular X-linked genes equal between XX and XY genotypes. Details are given in ref.2.

In *Drosophila melanogaster*, the Bridges ratio, X/A, is central to both sex determination and X-chromosome dosage compensation. Sex-specific lethal mutations such as *mle* and *Sxl*^{f1} affect both sex determination and dosage compensation, demonstrating that some genetic elements are common to the two processes[4,5]. Thus it appears that sex determination and dosage compensation may be two facets of the same regulatory process. A plausible genetic regulatory model has been proposed for intracellular measurement of the X/A ratio and the remarkable phenotypic effects of certain of these mutations[6]. An attempt has been made to interpret mammalian X inactivation in terms of this model, on the assumption that X inactivation also is based on some type of ratio measurement or intracellular counting of chromosomes[7].

The Grand Menhir re-examined

Sir—Commenting on P.G. Bahn's alerting us[1] to C. T. LeRoux's discovery that the capstones of three tombs in Brittany once formed a single decorated 14m long menhir, one of the decorations being a carving of a *hache-charrue* (axe-plough), I suggested in *Scientific Correspondence*[2] that Le Roux's discovery requires a reexamination of the date and function of the over 20m long now fallen and broken menhir called the Grand Menhir Brisé. My suggestion assumed the validity of the assertion first made by R.S. Minot[3] and then by E. Twohig[4] that there is also a *hache-charrue* carved on the latter menhir.

I recently examined the Grand Menhir Brisé and could not discern a *hache-charrue* carved on it even after I checked my observations against the sketch by Minot in his 1965 article and against the small scale drawing furnished to me by Twohig. There are unevennesses on the surface of the granite of the second fragment of the Grand Menhir Brisé (counting the largest fragment as the first fragment) which may be interpreted as possibly depicting an axe head, but there is no indication that these are man-made rather than natural, and the presence of the rest of the alleged *hache-charrue* seems to depend upon the imagination of the beholder[5] (See *Hamlet*, Act 3, Scene 2, "Shape of cloud").

Twohig, in the course of her careful and thorough research, did not always find carvings reported by Minot to be genuine, (personal communication) and Minot's sketch of the alleged *hache-charrue* differs from Twohig's drawing in substantial ways, including not showing a loop on the haft. Because of its size and weathered nature, Twohig did not make a rubbing, photograph or full-scale tracing of the alleged carving, and the small scale drawing on which she bases the drawing in her book reflects what she saw but does not necessarily record what others will see.

One further observation should be made. LeRoux interprets the three granite fragment now serving as capstones of La Table des Marchands, the tomb of Gavrinis, and the tumulus of "er-Vinglé", as having once formed a single carved *menhir*. R.J.C. Atkinson suggests that the three granite fragments determined by LeRoux to once have been a single standing stone was a very long *capstone* which was later broken, its fragments then used as capstones in three separate tombs (personal communication). A very long capstone would be consistent with the shape of the stone when unbroken, and we know that dolmens were constructed which could utilize very long capstones, such as Le Grand Dolmen at Bagneux (Maine-et-Loire).

Atkinson points out that menhirs, unlike upright stones and capstones used in tomb construction, do not have carvings on them, except, in rare instances, for some markings at the base, and certainly not halfway up the menhir. In such event the date of construction of the Gavrinis tomb of about 5200 to 5000 BP would be irrelevant to the determination of the date of erection of the Grand Menhir, and a possible date of about 3600 BP initially proposed by Alexander Thom[6] and A.S. Thom in connection with their lunar observatory hypothesis would not be affected by LeRoux's discovery.

Nature's Guide to How Britain Runs its Science

The latest edition of this popular wallchart is now available. The guide provides a comprehensive survey of the administration of British science, showing at a glance the functions, key personnel and finance of government departments, public and independent bodies, and the research councils. It has been thoroughly updated to take account of the many changes in structure and personnel that have occurred since the previous edition was published in 1983.

Copies are available from: Nature, Brunel Road, Houndmills, Basingstoke, Hants, RG21 2XS, UK. Prices: £4.75 (UK), US$8.50 (USA and Canada), £5.75 (all other countries). Airmail despatch outside the UK. Payment with order please. □

Intellect in evolution

Douglas J. Futuyma

Evolution: Essays in Honour of John Maynard Smith. Edited by P.J. Greenwood, P.H. Harvey and M. Slatkin.
Cambridge University Press: 1985. Pp.328. £30, $49.50.

By the fertility and originality of his thought, the variety of his interests and contributions, and the influence of his effervescent personality on his colleagues and students, John Maynard Smith has taken his place as one of this era's leading evolutionary biologists. His empirical and theoretical contributions have included functional morphology, *Drosophila* genetics and cytology, the genetics of developmental patterns, the evolution of senescence, the theory of polymorphism, speciation, evolutionary rates, and kin and group selection, the evolution of sex, and the evolution of behaviour. This *Festschrift* in honour of Maynard Smith on his imminent retirement from Sussex University therefore marks the end of an era.

Maynard Smith, perhaps more than any other single individual, has embraced both major strategies of explanation of evolutionary change: the formal theory of population genetics, including natural selection; and the phenotypic theory of adaptations. This second theory of adaptive strategies is largely devoid of genetics, but attempts to predict, for real phenotypic characters, the ordering of fitness values that appear as abstract constructs in population genetics. Both of these approaches, between which there is considerable tension, are represented in this collection.

The power of population genetics is revealed in Slatkin's theoretical treatment of the role somatic mutation might play in defending plants against attack by creating genetic mosaics (he concludes it will usually have little effect), and by Bengtsson's review of the number of underdominant loci required to establish a sterility barrier to gene flow between incipient species (generally many are required). These essays exemplify Lewontin's point that the role of population genetic theory is not to predict evolution, but to delineate the prohibited and the possible. Lewontin is less encouraging on the ability of theory to explain observations (for example to specify causes for gene frequency distributions), but is hopeful that variation at the nucleotide level may "give a finer structure of genetic detail corresponding to the detail that is built into the theory". Yet the theory includes elements such as population size, gene flow and linkage disequilibrium that surely will never be known in such detail, so the scope for such optimism may be rather narrow.

Representing the population genetic approach to adaptations, Felsenstein provides an intriguing distillation of theories of recombination, with some surprising conclusions (for example, the sib-competition model of Williams is a special case of Fisher and Muller's theory). Michod and Sanderson develop a theory of behavioural structure that obviates the need for kin selection as a necessary explanation of cooperation. Rose reviews his work on the genetics of senescence.

Maynard Smith: a view of both major strategies of explanation of evolutionary change.

Strategic analysis has become one of the chief tools in the study of adaptations, and Maynard Smith's introduction of the evolutionary stable strategy (ESS) concept is surely one of his most important contributions. The pitfalls lie not so much in the theory, which like population genetics theory varies in the realism of its assumptions, but in the testing, especially by the comparative method. Charnov shows the power of ESS theory to predict sex ratio and related phenomena, and uses the comparative method to good advantage. Packer and Pusey make a fairly convincing case for the ability of ESS theory to predict the outcome of asymmetrical contests in social mammals.

But observations do not always conform to the theory, as both Clutton-Brock and Parker and Hammerstein note, or they may conform for the wrong reasons. For example, Silvertown cites the composite *Hypochoeris glabra* in support of the hypothesis that the proportion of far-dispersing fruits should increase with fruit number because of density-dependent competition. But because near-dispersed fruits develop only on the circumference of the capitulum, the conformity to expectations is a necessary allometric consequence of the ratio of circumference to the area.

In other instances, the sensitivity of the test is inadequate. For example, D. Charlesworth attempts an admirably careful test of the hypothesis that dioecy has evolved in angiosperms as an outcrossing mechanism, by seeing if it is negatively correlated with self-incompatibility across families and genera. The data are inadequate for the test, but even if they were adequate, a census of this kind is not sufficient, because a phylogenetic analysis is required in each case to infer whether dioecy arose in a self-compatible or self-incompatible ancestor.

We are now all aware of the excess of overenthusiastic adaptationism, and of the difficulties of testing strategic theories of adaptation. But the theory itself may prove to have important limitations, as Parker and Hammerstein point out in an excellent review of evolutionary game theory. For example, realistic extensive games in which the current decision depends on previous events typically have multiple stable solutions. Thus the historical contingency of evolution is inescapable, even in optimality models. Parker and Hammerstein also note that the necessary synthesis of strategic theory with population genetics has not yet occurred and may prove difficult – as the schism within this book bears witness

Among the remaining essays, some fall within these two approaches: Seger presents a very restricted genetic model of sympatric speciation, León theorizes on seed germination, Gittleman reviews possible advantages of aggregated placing of young by mammals, and Greenwood and Wheeler offer a highly speculative physiological explanation of sexual size dimorphism in homeotherms.

A potpourri of other contributions includes an exemplary exercise in adaptive hypothesis testing by Harvey and Ralls concerning body size in weasels, an intriguing failure by Bradbury, Vehrencamp and Gibson to find a mechanistic basis for the variance in male reproductive success in lek-forming species, an elaboration by Stenseth of Maynard Smith and Stenseth's theory of lag-load and evolutionary rates, and a benediction by May.

This well-edited volume offers a nicely balanced overview of some of the most active areas of investigation of adaptation. Like most honorary volumes, it is neither deep nor comprehensive, but several of the essays, as I have described, are important and thoughtful, and will surely be cited widely.

Action at a distance in public affairs

Joseph Haberer

Einstein in America. By Jamie Sayen. *Crown: 1985. Pp.340. $17.95.*

OF Einstein it may be said that "fame was the spur" for his life-long involvement in matters relating to political and social issues. In 1920, with his sudden and unanticipated emergence as a world figure, he recognized that his name and celebrity status could be used as a means to shape public opinion and influence those who made decisions on issues with which he was concerned: notably, war and peace; Zionism and the Jewish people; social and economic justice; the threat of fascism and Hitler; the responsible and humane use of scientific knowledge.

Einstein's fame took hold first and especially in America. It is his relationship to the country of his eventual adoption that is at the centre of this biography. In 20 chapters Sayen explores thoroughly and with great acumen the many aspects of Einstein's experience with and in America: from the first journey in 1921 (with Chaim Weizmann, to raise money for the Hebrew University and publicize the Zionist cause) to his last effort in 1955 with Bertrand Russell through a Manifesto to warn against the dangers of the arms race. Most of the book deals with the years after Einstein settled in America in 1933, but three chapters cover the years prior to his arrival and provide an excellent background to the American phase.

Sayen's book is the first to deal primarily with Einstein's various political activities during his mature years, and since there was no intention of writing a complete biography little attention is given to Einstein's scientific work (Abraham Pais's *Subtle is the Lord*, published in 1982 by Oxford University Press, has done this superbly). Sayen demonstrates a thorough grasp of the Einstein materials and literature; evident throughout is his careful and impressive use of the large correspondence from the Einstein Archives. Earlier biographies, most notably Ronald Clark's *Einstein: The Life and Times* (World Publishing, 1971) were clearly deficient in this regard, and are quite misleading on several important aspects of Einstein's political life.

The Einstein that emerges in these pages is a brilliant scientist, as one would expect; a man with a finely honed sense of social responsibility; a person of great warmth, kindness and modesty. We know however, remarkably little about his deeper self and he seems to have gone to considerable lengths to keep it that way. But we know of some problems, most notably his life-long failure to establish intimate personal relationships. Sayen shows Einstein with some of his flaws, and thus avoids the all-too-frequent hagiographic accounts that have come our way.

There is a widely held view that Einstein's political perceptions and activities were those of a man filled with good intentions but characterized by a rather naive grasp of politics and social issues. Sayen lays this myth to rest. Einstein clearly made it his business to be well-informed on those matters on which he took a public stand or in which he became otherwise engaged; he would not, for example, sign petitions, write references or support causes unless he had satisfied himself thoroughly that the facts were such that he could in good conscience do so. He was fully aware that his name was his credit, and he made every effort not to squander it. To be sure he made some mistakes, but he learned quickly to be more careful, and it is remarkable how seldom he erred in his assessments of people and events.

Einstein was the progenitor of the scientist as a publicist for the causes with which he identifies. He wrote (for a scientist of his day) extensively in the press on social and political subjects, and kept up a flow of correspondence in which he addressed important questions of the time. Sayen's book demonstrates that Einstein's understanding of the political and social realities of the twentieth century, as well as his underlying philosophical positions, were much keener and showed a better grasp of the emerging forces than those of most of his critics. For example, his attitude towards the Soviet Union was sympathetic towards its socialist objectives, but from the early 1920s — long before the Stalinist excesses — he was quite aware of the human rights abuses. He refused in the 1920s to sign petitions attacking right-wing excesses unless they included criticism of those of the left also. But he argued in the post-1945 period that an accommodation with the Soviet Union was imperative for a lasting peace, though he recognized the obstacles on both sides that stood in the way. His reluctance to criticize the Soviet Union publicly during the Cold War period was based on complicated reasoning, but came down essentially to an unwillingness to add fuel to the anti-communist hysteria in America.

Although Einstein understood politics, he appears to have thoroughly disliked the activity and the process. He took positions, but avoided choosing parties, or becoming a partisan. Perhaps he resembled somewhat the platonic philosopher-king, who reluctantly, but out of perceived necessity, enters the tainted and turmoil ridden world of the political. He sought to influence while keeping his distance. ☐

Joseph Haberer is Professor of Political Science, Purdue University, West Lafayette, Indiana 47907, USA.

Close considerations

Jack Cohen

Biology of Fertilization. Edited by Charles B. Metz and Alberto Monroy. *Academic: 1985. Three volumes, pp.391, 475 and 469. $75, £75 each volume.*

IN THE late 1960s, a number of people, myself among them, moved from other fields of developmental biology into research on fertilization, partly because electron microscopical techniques were dramatically illuminating the magic moments of membrane fusion but also because mammalian gametes were just becoming accessible to experiment. *Concepts of Fertilization*, edited by Monroy and Metz and published in 1967, was a guide book to the territory for us. That collection of authoritative, and revelatory, review articles by all the "big names" put the subject in context and provided both opinion and forecasts; it did not have the now-fashionable tone that "for each expert there is an equal-and-opposite expert", with each disagreement referenced and written in the dense prose which now seems mandatory for the professional review. The editors were daring, for that time, in assembling biochemists, botanists and electron-microscopists, as well as fertilization specialists, and in suggesting that work upon bacteria, algae and *Paramecium* could illuminate sea urchin and mammal fertilizations.

This new collection, which comes in three volumes entitled *Model Systems and Oogenesis, Biology of the Sperm* and *The Fertilization Response of the Egg,* looks very different. We have all got older, and we now know much more. But beyond that I believe there is a much more basic and serious difference. As an area of science develops, knowledge should not simply accumulate; generally accepted theories should encompass large areas of previously disparate observations and bring them into a coherent framework. New textbooks then reflect this coherence in their examples for students. There have been several attempts in the area addressed by this collection, of which Austin and Short's series *Reproduction in Mammals*, now going through a second edition, has probably been the most successful.

For me, this new collection of reviews fails because it gives only sporadic indications of the larger view. The density of information, argument and referencing of most of the articles is appropriate to the subjects they consider, and these articles could well have been found in the *Advances in . . .* or *Current Topics in . . .* sort of book. What is missing is the ultimate rather than the proximate consideration. All the authors, even those considering polyspermy and its prevention, write of *the* sperm and *the* egg, and the failure of the vast majority of gametes to fertilize is never invoked in arguments about the few which do and the mechanisms they seem to use. Similarly, the enormous variety of mRNA elaborated by the oocyte's diploid (maternal) genome and stored in mysterious ways for use by the cleaving embryo is explained as the proximate mechanism to supplement the mRNA-synthetic abilities of the single zygote nucleus, in the immense egg cytoplasm, until such time as the nuclei have multiplied. Surely the theoretical importance of early development being controlled by maternal genome, only mentioned by Monroy, could have been expanded somewhere? The titles of the individual reviews often promise such a general approach — "Nucleo-cytoplasmic interactions . . .", "Activation of DNA synthesis . . .", "Regulation of mammalian spermatogenesis", "Vertebrate sex determination" — but each focuses down on one problem and doesn't usually generalize in the Discussion section either; there are too many "More work is needed before meaningful generalizations . . ." conclusions. If this is so, then this is not the time to review that subject.

The reviews seem mostly to have been written in about 1981, and to have been updated in 1983–1984; later references are nearly always to the author's own work. This is inevitable in such a grand compilation, but it makes the previous criticisms much more serious. Generalities, indeed prejudices, of workers of this eminence will usually keep their interest for some years, but these minor issues lose immediacy much sooner. Particularly unfortunate in this context is the absence of the inositol triphosphate (IP3) story of 1984, which provided a new second messenger with close affiliations to the cell membrane; it rendered incomplete nearly all of the controversy about Ca^{++}, much of that about membrane receptors of egg or sperm, and all of that about phospholipid involvement in sperm maturation. An attempt by Whitaker and Steinhardt to make good this particular deficiency by way of an addendum to their Chapter 5, printed at the end of Vol. 3, only succeeds in emptying this can of worms among all the other contributors: tangled discussions of cytoplasmic pH, Na$^+$/H$^+$ exchange and egg activation/cortical reactions, and even the bindin story, are shown to have been incomplete, needing identification of this crucial thread. If theories had been proposed, IP3 would have added mechanism; as it is, for most of the articles subsequent discovery invalidates much of their content.

There is certainly a place for this collection in university libraries, and even in the more specialized collections of directors of (rich) *in vitro* fertilization units, while individual articles will be very valuable, especially for research students. But what a pity it is that they will miss the real expansion of mental horizons which we gained from the first edition. ☐

Products of history

Janet Browne

Seeds of Change: Five Plants that Transformed Mankind. By Henry Hobhouse. *Sidgwick & Jackson: 1985. Pp.245. £15. To be published in the United States later this year by Harper & Row.*

POTATOES are not usually given much thought beyond the kitchen table, yet in Henry Hobhouse's *Seeds of Change* they take on a starring role. Rightly so, for these humble tubers have had a dramatic part in world events. The blight of 1845 meant nothing less than starvation for the Irish nation; economic crisis erupted in Britain, forcing rapid tax reform, repeal of the Corn Laws and a temporary halt to restrictive trading practices; and on a larger scale, one more wave of hopeful settlers emigrated to the United States where they then went on to become a recognizable force in the shaping of modern America.

There are other plants, other commodities that have changed the course of history and, of these, Hobhouse selects a further four to illustrate his general theme that plants matter more than one might think. Sugar cane in the West Indies, a crop supported by an economic and social superstructure of plantations and slavery, was, by his account, responsible for the infamies of the slave trade and for nearly half of all the seagoing effort, naval and civil, of western European countries before 1830. It gave Britain commitments in the Caribbean that Hobhouse feels she could well have done without (and an irredeemably sweet tooth). Cotton, on the other hand, made the American south rich and confident. This too was a cash crop based on slavery, contributing to a lifestyle that was ripped apart by the Civil War and yet, ironically, feeding the first great industrial revolution with raw material for newly mechanized processes of textile production.

Then there is tea. The British tea trade with China during the eighteenth century heralded not only imports of porcelain ("china"), opium and redesigned "clipper" ships, but also a fight for economic supremacy with the Dutch East India Company, encouraging Britain to concentrate primarily on India, and the opium wars of 1840–1842 that finally opened up two British footholds in China — Shanghai and Hong Kong. Last of all, although first in his book and undoubtedly Hobhouse's most interesting chapter, there was the hunt for quinine, the bark of a South American tree which prevents and cures malaria, thereby allowing the opening up of great tracts of central Africa and India to European colonial powers.

There is much here that will be fresh, surprising and intriguing to most readers whatever their background. The stories of these staple products are extraordinarily rich, containing within them all kinds of repercussions that echo through to the present day. But for professional historians, perhaps for scientists too, the book is hampered by Hobhouse's all-pervading sense of moral outrage at the activities of our ancestors, and his implicit assumption that things are better now. Perhaps his forthcoming sequel (on corn, oil and wine) will be less Anglocentric and less judgemental. Many readers will surely wish for something more of an analysis of the actual causes involved in, for example, the colonization of India; the ability to control malaria through quinine, critical as it may have been, is hardly a reason for India's emergence as the jewel in the British Crown, any more than it is an explanation for the scramble for Africa. Hobhouse's breezy good sense is no match for the deeper causes lurking here. ☐

Connecting with the invertebrates

Adrian Horridge

Model Neural Networks and Behavior. Edited by Allen I. Selverston. *Plenum:1985. Pp.548. $69.50, £66.03.*

THE scope of this book is less than the title suggests and limited largely to central nervous mechanisms in invertebrates. More than 20 of the contributors are from the US west coast and the same number work during summers at Wood's Hole. The dedication to Graham Hoyle is apt. In some sense it represents a panegyric of collective achievement as the topic has developed several important cutting edges, because, in Selverston's words, these invertebrate systems have "characteristics especially suitable for answering specific questions".

The qualitative analysis of real connections between actual neurones in favoured invertebrate preparations, and the origin of these patterns in development and inheritance dominate the scene. Fundamentally the book is an expression of the reductionist approach, in which analysis goes from detail to detail, down to actual mechanical causes by every available technique. The chase leads into topics such as the "activity-dependent enhancement of synaptic facilitation" as the mechanism at the point where learning actually occurs, to long-lasting effects of synaptic modulators, to cyclic AMP and calcium ions. In the growth studies, the editor has selected accounts of marking membranes with antibodies which reveal that neurone surfaces differ chemically, but the reductionism is non-quantitative, an interesting paradox.

With this type of analysis, an important feature is the commonality of the results. Almost every one of the 27 papers concentrates on a different preparation but the results seem to be comparable. We begin to understand that there are only a limited number of mechanisms, presumably based on a limited number of conserved DNA sequences, which generate channels, transmitters, receptors on membranes, hormones, and units in a construction set. After a century of effort, we understand many of these components; by contrast, we are just at the threshold of the chemical mechanisms that bring and hold the pattern of connections together. The final chapters on neurogenetics are excellent snippets of a fast-moving and fascinating topic.

As an exercise to demonstrate the importance of invertebrate preparations to our understanding of nervous systems, the volume is a great success. Identifiable neurones, large enough to be dissected out singly and analysed for chemical content, have pushed our understanding much further than is possible with vertebrates.

That statement applies to much besides the contents of this book, notably to sense organs and sensory processing. For this volume has nothing on information flow, signal-to-noise ratios, or on the optimization of the neural networks. The software is all molluscan: the hardware chitinous. Those recording from anonymous mammalian neurones of medical interest get on-line computers whereas those slogging to elucidate the exactly identified invertebrate neural circuits pursue a task which one of them rightly recognizes as "a long and irksome process". But neural networks, surface-specific molecular interactions in growth, and polypeptide sequences are also topics where an enormous amount of tedious fact-finding must be done before elegant generalizations can be reached, simply because the human understanding has no ready-made models for ordering these new bodies of data.

There are seven chapters dealing with neural circuitry, nicely spread between leech, molluscs, locust flight motor and the lobster pyloric ganglion. Again this is essential foundation work, defining the components, that opens up studies of growth, learning, plasticity, transmitters and membrane biophysics. Later sections in the book deal with all these topics. Development studies, cellular chemistry and membrane biophysics are again spread between insects, a mollusc and leech. Analysis of learning in circuits of identified neurones is restricted to molluscs, where work has consolidated over the past decade. Even neurogenetics now spans three phyla.

Unfortunately the presentation is often lack-lustre; lacking any introductory concessions, lacking spice, lacking a real philosophical backing, and certainly lacking a historical perspective or even a decent index. Essentially a result of lack of thought, it is today characteristic of much scientific writing done as an account of ongoing activity, out of date in five years. I suspect many of the circuits described are oversimplifications. Nowhere in the book is there a consideration of how to analyse neurone function. I am frustrated however that my own student, whom I have tried to interest in this problem, states that "this is the wrong type of question".

There are 60 contributors, among them most of the best specialists in the field, and there are many excellent contributions. The whole book is a splendid summary of ongoing activity at an expert level contributing to the understanding of many aspects of all nervous systems. The book should be read by all who try to make sense of how central nervous systems are really put together in the non-mathematical non-engineering sense. □

Delayed responses

P.F. Baker

Calcium in Biological Systems. Edited by R.P. Rubin, G.B. Weiss and J.W. Putney. *Plenum:1985. Pp.737. $89.50, £85.03.*

COMING to grips with the many roles of calcium is just another task the modern biologist must master. This volume is based on the proceedings of a "calcium theme" included in the 67th Annual FASEB meeting held in Chicago in April, 1983. It includes 80 contributions divided into three sections: metabolic and functional aspects, regulation of muscle contractility, and nutritional and pathophysiological aspects of calcium action..

In general, the choice of contributors and contributions — which range from calcium chemistry and biochemistry to clinical medicine — are excellent, although readers would have benefited from a few more overviews setting specific topics in perspective. A far more important criticism, however, is that the meeting was held in 1983 and the book only appeared in 1985, two whole years later.

For a field that is changing as fast as calcium such a delay is unacceptably long and, unfortunately, robs the book of much of its value. This is very sad as the book contains a great deal that would have been highly topical in 1983 or even 1984, but by now has largely reached the scientific community by other means. Nevertheless, it says much for the editors' choice that there is still material of considerable interest and the volume clearly delineates the ubiquitous and pivotal role of calcium in diverse physiological and pathological states. It is only a pity they did not convince their publishers that for those intending to purchase a book of this type, its value is inversely related to the delay between the meeting and its publication.

P.F. Baker is Professor of Physiology at King's College London (KQC), Strand, London WC2R 2LS, UK.

- A recent volume in Humana's *Contemporary Biomedicine* series is *Calcium and Contractility: Smooth Muscle,* edited by A.K. Grover and E.E. Daniel. The book is a collection of reviews by well-known figures in the field and contains, says the publisher, "Incisive synthesizing summaries of the powerful outpouring of research on cell contractility today". Price is $64.50 in the United States, $74.50 elsewhere.

Rim syncline volume estimation and salt diapirism

Kai Sørensen*

Geologisk Institut, Aarhus Universitet, DK-8000 Århus C, Denmark

Quantitative studies of salt structures are based on the assumption of a simple relationship between excess sediment volumes and the volumetric growth of salt structures. This assumption is inadequate and, instead, this article shows how the excess volume relates to the volume swept out by the deforming sediment surface and the moving salt/sediment interface. The use of this new basis for volume reckoning is demonstrated, and its implications for waste disposal, hydrocarbon exploration and tectonic subsidence studies are emphasized.

SALT pillows and salt diapirs occur in great numbers in several sedimentary basins. The movement of salt dramatically changes the depositional geometry of its enclosing basin, creating, for example, structural traps for hydrocarbons. Salt structures are also considered suitable sites for the disposal of high-level nuclear waste. Thus, there are compelling reasons for studying such structures.

Studies of natural salt diapirism are built on the classic work of Trusheim[1,2] who demonstrated how the history of a diapir can be unravelled by observing the location and timing of excessive sediment thicknesses, assuming these to be caused by subsidence over a depleting source layer. The main features of Trusheim's model are illustrated in Fig. 1 (*b*, *c*). In the pillow phase[1], excess sediment volumes are deposited in the primary rim syncline (V^1_{rs}), far from the centre of the structure (Fig. 1*b*). The excess volume (V_{ex}) is defined as the rim syncline volume (V^1_{rs}) minus the 'regional normal' (V_{rn}). 'As measured' sediment volumes must be corrected for compactional effects. The amount of finitely displaced salt (V_{st}) is the volume of salt above the original source layer (of thickness s_0). The diapiric-phase rim syncline (V^2_{rs}), the secondary rim syncline[1], is characterized by excess volumes adjacent to the diapir (Fig. 1*c*). It is overlain by an only slightly structured rim syncline (V^3_{rs}) of the post-diapiric phase, the tertiary rim syncline. Trusheim's model is qualitative, but its quantitative potential was realized "*Das Volumen des akkumulierten bzw. extrudierten Salzes entspricht in jeder Phase dem der Sedimente, die diese Bewegungen kompensieren, sofern man die epirogene Absenkung subtrahiert*" (ref. 1, p. 145). Although Trusheim's 'volume rule' has been used by several authors[3-7], there has been no systematic discussion of volume estimation. This article aims to start such a discussion and, using an example, to demonstrate its relevance. The volume discussion is generally valid, but the diagrams illustrating it (Figs 2, 3) are two-dimensional, that is, areas sum in the figures as volumes in the general discussion.

Pillow phase

Analogous with experimental diapirism[8], it is hypothesized that a salt pillow outlines the growth stages (Fig. 2*a*) whose surface expression is a laterally extending sink and narrowing source. The salt and sediment displacement volumes are laterally extended and do not overlap vertically, so that the following equation can be considered valid for volumes summed over the entire salt intake area (Σ_a) and over time (Σ_t)

$$\Sigma_a\Sigma_t V^1_{sk}(=\Sigma_a\Sigma_t V^1_{sc})=\Sigma_a\Sigma_t V^1_{sdd}(=\Sigma_a\Sigma_t V^1_{std}) \qquad (1)$$

where the superscripts designate the pillow phase. Complexities in volume estimation arise because such physically real volumes as, for example, the sink volume, have to be related to the measurable excess volume, which is an operationally defined construction.

The growth stages envelop an 'overlap volume', acting first as a sediment source and then as a sediment sink (surface overlap volume, V_{so}). A corresponding overlap volume (displacement overlap volume, V_{do}) is enveloped by the subsurface salt-sediment interface. Within the displacement overlap volume, sediments are first displaced by salt, then salt by sediments.

The overlap volumes 'measure' the path of the structure (Fig. 2*a*). Whether the surface overlap volume is reflected in the excess rim syncline volume depends on the regional rate of sedimentation. Two extremes can be envisaged.

First, when the regional rate of sedimentation (v_{sd}) is zero (Fig. 2*b*), uplift within the surface overlap volume leads to erosion of the pre-pillow series ('pre' of Fig. 2*a*), so that the cumulative excess sediment volume is equal to the cumulative sink volume (Fig. 2*a*, sum of arrowed prisms). This, in turn, is larger than the volume of finitely displaced salt (V_{st}) by an amount equal to the surface overlap volume (Fig. 2*a*), so that

$$\Sigma_a\Sigma_t V^1_{ex}=\Sigma_a\Sigma_t V^1_{sk}=V^1_{st}+\Sigma_a\Sigma_t V^1_{so} \qquad (v_{sd}=0) \qquad (2)$$

Second, when the regional rate of sedimentation exceeds the rise rate of the structure (v_{up}), the uplift within the surface

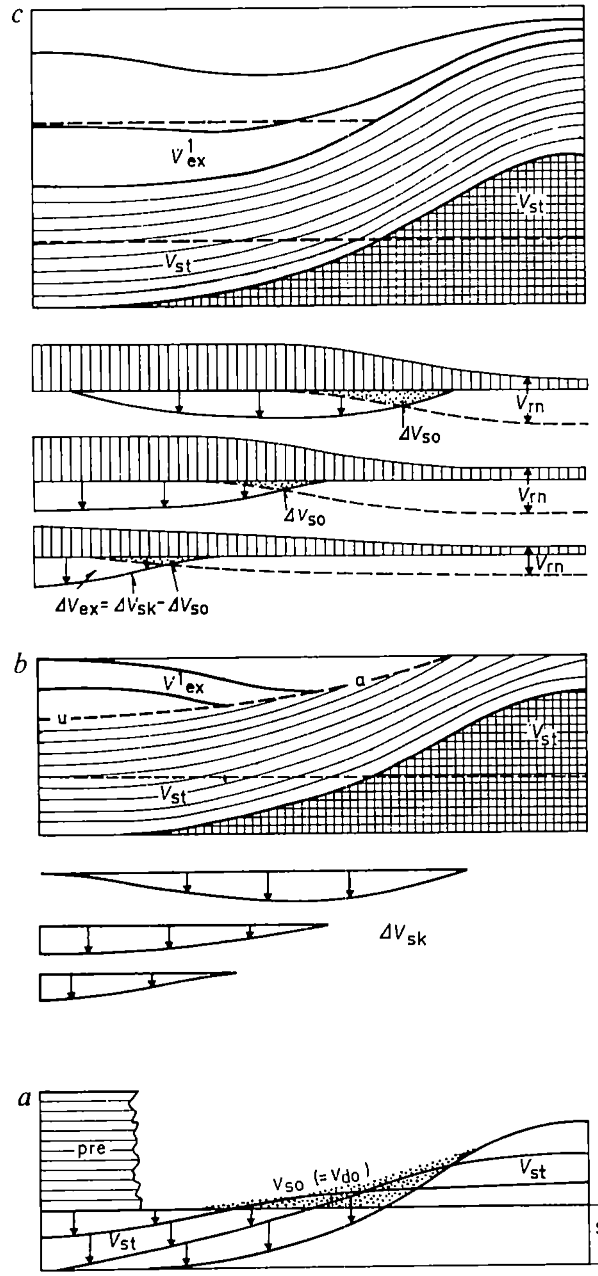

Fig. 2 Pillow phase volume estimation. *a*, V_{so}, surface overlap volume; V_{do}, subsurface displacement overlap volume. Pre-pillow series (pre) and source layer thickness (s_0). *b*, Pillow formation with no regional sedimentation. The excess volume (V^1_{ex}) is equal to the sink volume ($\Sigma\Delta V_{sk}$) but larger than the displaced salt volume (V_{st}). Note the angular unconformity (au) between rim syncline layering and the pre-pillow series. *c*, Pillow formation with the regional rate of sedimentation larger than the salt uplift rate. The excess volume (V^1_{ex}) is smaller than the sink volume ($\Sigma\Delta V_{sk}$) by an amount equal to the overlap volume ($\Sigma\Delta V_{so}$) but equal to the displaced salt volume (V_{st}). This limiting case is similar to the pillow phase of Trusheim's model (see Fig. 1*b*). Note the absence of angular unconformities. Arrows define cut-out volumes.

overlap volume causes a regional sedimentation (Fig. 2*c*, vertical ruling) less than normal (V_{rn}, Fig. 2*c*). When deriving the excess volume by subtracting a constant regional normal (Fig. 2*c*, vertical ruling plus stippled) from the rim syncline volume (the "epirogene Absenkung" of Trusheim[1]), the excess volume becomes (see Fig. 2*c*)

$$\Sigma_a\Sigma_t V^1_{ex} = \Sigma_a\Sigma_t V^1_{sk} - \Sigma_a\Sigma_t V^1_{so} = V^1_{st} \qquad (v_{sd} > v_{up}) \tag{3}$$

Only in this case will the compaction-corrected excess volume be equal to the finite amount of displaced salt. For the pillow phase, in general, equations (2) and (3) combine to give

$$V^1_{st} + \Sigma_a\Sigma_t V^1_{so} \geq \Sigma_a\Sigma_t V^1_{ex} \geq V^1_{st} \tag{4}$$

As illustrated in Fig. 2, the internal structures of the primary rim syncline can be expected to differ significantly in the two cases, although the sink volumes of both cases, Fig. 2*b*, *c*, (triangular prisms with arrows) are equal. In the first case, angular unconformities between the layering of the primary rim syncline and the layering of the pre-pillow series develop. In the second case, the primary rim syncline will be characterized by converging and diverging layering. It should therefore be possible to decide which side of equation (4) the excess sediment volume of a specific structure approaches.

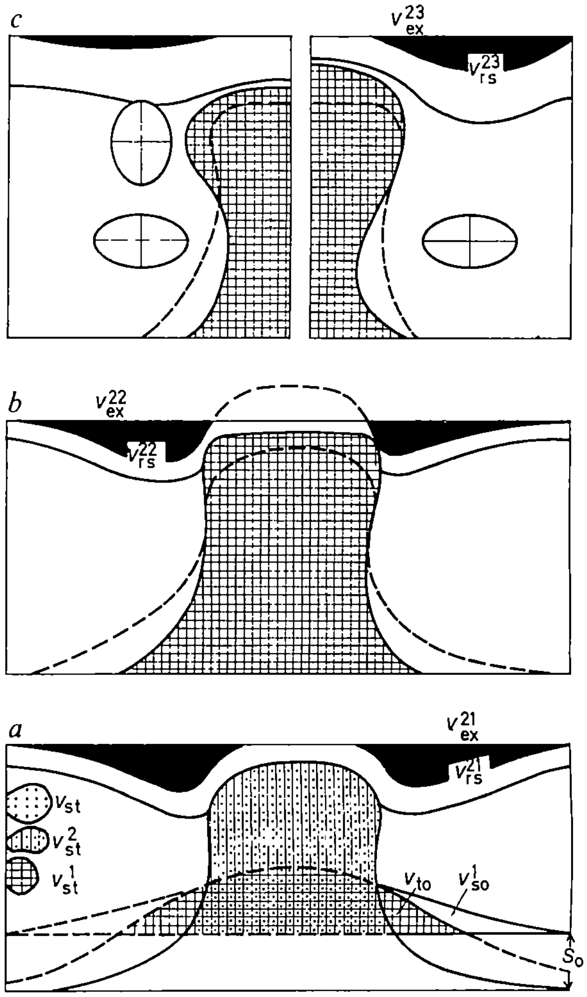

Fig. 3 Three modes of the diapiric phase. *a*, Intrusion mode; its rim syncline (V^{21}_{rs}) and its excess volume (V^{21}_{ex}). V_{so}, Surface overlap volume; V_{to}, transition overlap volume; V_{st}, salt volumes. *b*, Dissolution mode; its rim syncline (V^{22}_{rs}) and its excess volume (V^{22}_{ex}). *c*, Overhang mode; its rim syncline (V^{23}_{rs}) and its excess volume (V^{23}_{ex}). Right, overhang formation by necking. Left, overhang formation by combined necking and top spreading.

Diapiric phase

Trusheim suggested that the transition from the pillow to the diapiric phase was discontinuous, the pillow formation leading eventually to a fault-controlled breakthrough. If the diapir develops without significant lateral movements, overlap volumes are not formed. In this phase, the excess volume therefore corresponds to the sink volume. But other types of volumetric discordances may develop. They can be described with reference to three 'modes' of diapirism (Fig. 3). Real diapirs are likely to alternate between the intrusion and dissolution modes after

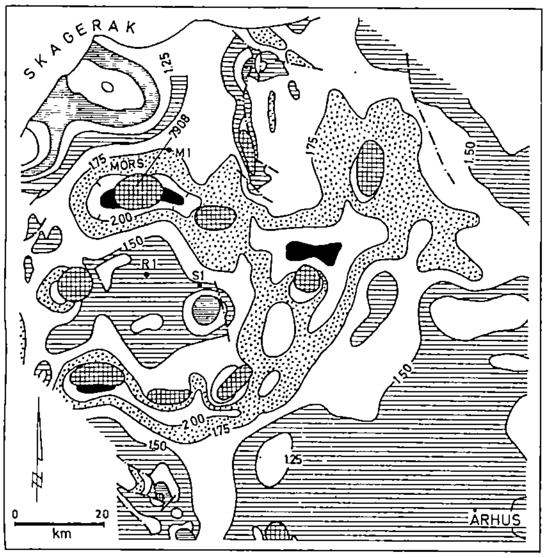

Fig. 4 The Danish onshore salt structure province. Cross-hatched, salt diapirs. Contours, two-way-travel time in seconds to the Gassum Formation reflector. The Gassum reflector is undisturbed under the Århus-Silkeborg Flat (west of Århus)[19] and under the Rødding Flat (south of the well R1)[14]. Deep wells mentioned in the text: R1 (Rødding 1), M1 (Mors 1) and S1 (Skive 1). 7908, seismic profile discussed in the text. Simplified after a map by Baartman, Olsen and Woodward (in ref. 20).

initial intrusion, and overhang formation may occur in combination with both intrusion and dissolution.

In the 'intrusion mode' (Fig. 3*a*) the following equalities hold

$$\Sigma_a\Sigma_t V^{21}_{\mathrm{ex}} = \Sigma_a\Sigma_t V^{21}_{\mathrm{sk}} (= \Sigma_a\Sigma_t V^{21}_{\mathrm{sc}}) = \Sigma_a\Sigma_t V^{21}_{\mathrm{sdd}} (= \Sigma_a\Sigma_t V^{21}_{\mathrm{std}}) \qquad \text{(intrusion mode)} \quad (5)$$

Because, by definition, no material transfer occurs across the fault plane, the sink volume must also be equal to the displacement volume (provided intrusion is fault-controlled). The first superscript designates the diapiric phase, the second, the mode.

For some combinations of overburden thickness, regional sedimentation rate and diapiric rise rate, diapirism leads to breakthrough (Fig. 3*b*) to the surface (extrusion) or to near-surface dissolution. In both cases, salt is dissolved, so that the surface source and sink volumes are no longer equal. The volume estimation formula for the 'dissolution mode' of diapirism must include this inequality which can become significant in two respects. If distant sources cannot supply material, lack of a nearby sediment source will lead to a deepening sink. In this stage, depositional patterns, which are entirely different from the regional pattern, may develop. Under some circumstances, petroleum source rocks can be anticipated in the rim syncline, in other conditions evaporite (re)deposition[9]. In this mode, salt diapirism may have a generic influence on sedimentation, and not the merely moderating influence suggested recently[6]. The discordance between source and sink volumes may also lead to delayed filling of the sink, in which case the possibility of excess sediments post-dating the age of the sink arises. The complete volume formula is therefore

$$\begin{aligned} &\Sigma_a\Sigma_t V^{22}_{\mathrm{sdd}} = \Sigma_a\Sigma_t V^{22}_{\mathrm{sk}} > \Sigma_a\Sigma_t V^{22}_{\mathrm{sc}} \geq 0 \\ &\Sigma_a\Sigma_t V^{22}_{\mathrm{ex}} \leq \Sigma_a\Sigma_t V^{22}_{\mathrm{sk}} \end{aligned} \qquad \text{(dissolution mode)} \quad (6)$$

Many diapirs are characterized by significant overhangs. In the Trusheim model[1], overhang formation is supposed to occur by spreading of the diapir top. Alternatively, its formation can be thought of as a consequence of source layer depletion leading to 'necking' (Fig. 3*c*, right)[10]. Finally, overhang formation may be the result of combined necking and top spreading (Fig. 3*c*, left). If so, the positive and negative displacement volumes are vertically superposed and the surface sink will be less than the subsurface displacement volume. If necking is the dominant process, a surface sink will develop. To the 'overhang mode' of diapirism the following relation applies

$$0 \leq \Sigma_a\Sigma_t V^{23}_{\mathrm{sk}} = \Sigma_a\Sigma_t V^{23}_{\mathrm{ex}} \leq \Sigma_a\Sigma_t V^{23}_{\mathrm{sdd}} \qquad \text{(overhang mode)} \quad (7)$$

Significant lateral movements during overhang formation must be accommodated by deformation of pre-existing rim synclines. The strain ellipses (Fig. 3*c*) illustrate, in a general way, the state of finite strain imposed on the rim syncline by the overhang formation. Consequently, accurate volume estimation for salt diapirs with significant overhangs requires identification of the mechanism of overhang formation.

Let us consider a diapir (say that of Fig. 3*a*) and apply Trusheim's volume rule to its entire development. His rule asserts that the total excess volume is equal to the amount of finitely

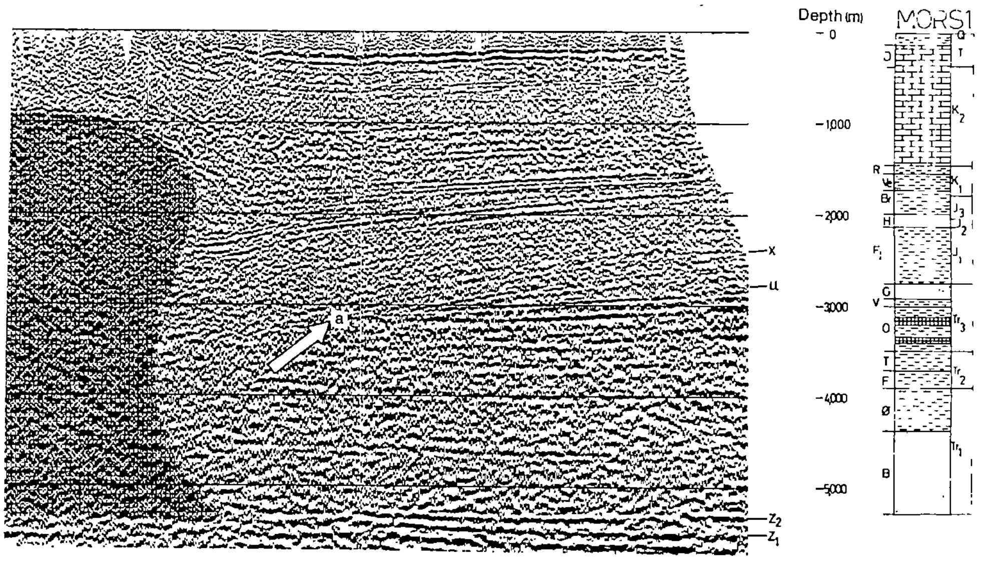

Fig. 5 Migrated and depth-converted seismic reflection profile 7908 (Fig. 4). Acquisition and data processing by Prakla Seismos. The horizontal layering below the on-lap unconformity (au) signifies the pre-pillow series on top of a depleted source layer. Reflectors z_1 and z_2 probably originate from carbonatic and sulphatic source layer remnants. The line 'au' marks an on-lap and truncation structure which is interpreted as marking the onset of source layer depletion (see Fig. 2*b*). The Mors well, terminated at a depth of 5,303 m below sea level, is located close to the northeastern termination of line 7908. Stratigraphy and lithology from refs 20-23. Lithology: dots, sandstone; bars, shale; dots and bars, sandy shale; bricks, chalk. Cross-hatched, evaporites. Lithostratigraphy: Bunter Formation (B); Ørslev Formation (Ø); Falster Formation (F); Tønder Formation (T); Oddesund Formation (O); Vinding Formation (V); Gassum Formation (G); Fjerritslev Formation (Fj); Haldager Formation (H); Bream Formation (Br); Vedsted Formation (Ve); Rødby Formation (R). Chronostratigraphy: T_1, T_2, T_3, Lower, Middle and Upper Triassic, respectively; J_1, J_2, J_3, Lower, Middle and Upper Jurassic, respectively; K_1, K_2, Lower and Upper Cretaceous, respectively; D, Danian. T, Tertiary. Q, Quaternary.

displaced salt (V_{st}, Fig. 3*a*). Following the volume estimation of this work, however, the total excess volume is

$$V^1_{st}+\Sigma_a\Sigma_t V^1_{so}+V^2_{st}\geq\Sigma_a\Sigma_t V^{1+2}_{ex}\geq V^1_{st}+V^2_{st} \quad (8)$$

in which $V^1_{st}+V^2_{st}$ is seen to exceed V_{st} by an amount equal to the volume defined by the original source layer surface, the pillow surface and the diapir surface. Terming this volume the 'transition overlap volume' (V_{to}), equation (8) becomes

$$V_{st}+\Sigma_a\Sigma_t V^1_{so}+V_{to}\geq\Sigma_a\Sigma_t V^{1+2}_{ex}\geq V_{st}+V_{to} \quad (9)$$

The excess volume is always larger than the volume of the salt which moved into the structure, so that Trusheim's volume rule, applied to a diapir, is incorrect, and only correct in the limit $v_{sed}>v_{up}$ when applied to a pillow structure (see equation (3)).

To obtain the excess volume as estimated above, it is necessary to correct the 'as measured' volumes ('am') for compaction: a correction due to the post-depositional compaction (post-correction, post(cc)) and a correction due to the syn-depositional compaction of the underlying sediments (pre-correction, pre(cc)). Post-depositional compaction leads to a positive post-correction equal in magnitude to the expansion of the unit in response to decompaction. Part of a unit under consideration is due to compaction of the underlying sediments, leading to a negative pre-correction. Then the compaction-corrected rim syncline volume (V_{rs}(cc)) is

$$V_{rs}(\mathrm{cc})=V_{rs}(\mathrm{am})+\mathrm{post(cc)}-\mathrm{pre(cc)}+\mathrm{er(c)} \quad (10)$$

including an erosional correction (er(c)). The excess volume, in its corrected form, is

$$V_{ex}=V_{rs}(\mathrm{cc})-V_{rn}(\mathrm{cc}) \quad (11)$$

where V_{rn}(cc) is the regional normal corrected by a procedure similar to that of equation (10). Depending on lithology and position within the sequence, the total correction may be negative, positive or zero. The correction to any interval including the surface will be negative if erosional effects are negligible.

Mors post-diapirism

From uncorrected rim synclines[1,5,7] it has been inferred that diapiric rates of 0.1-0.5 mm y^{-1} are typically followed by rise rates at least one magnitude less[5,7]. Trusheim[1] designated this 'slow tail' to diapirism as the post-diapiric phase, and its associated rim syncline as the tertiary rim syncline (see Fig. 1). Taking compactional effects into consideration, the question arises as to whether the excess volume of the post-diapiric rim syncline reflects salt structuring or whether it results from differential compaction.

The Mors salt diapir (Fig. 4) developed from a Zechstein source layer of unknown thickness (z_0). The profile to be discussed is derived from the seismic reflection profile 7908 (Fig. 5) which connects the Mors diapir with the deep well, Mors 1. The regional geology implies that the post-Oligocene history of the Mors area has been one of net erosion. It is therefore necessary to consider the effects of compaction on the 'post-diapiric' history, allowing for a non-vanishing erosion correction in equation (10). The decompaction calculations have been performed according to ref. 11. Maximum post-Oligocene erosion could have been ~300 m. Removal of the Upper Cretaceous (UC) section leads to an 'expansion' of the pre-UC section of Mors 1 of 596 m assuming zero post-Oligocene erosion and 676 m assuming an erosion of 300 m. The corresponding expansions of the section through the secondary rim syncline (Fig. 6) are 679 and 749 m, respectively. The difference in expansion between the primary (Mors 1) and secondary rim synclines (83 m and 73 m, respectively) is not very sensitive to variations in the erosion correction of the relevant magnitude. This difference in expansion constitutes the negative pre-correction to the 'as measured' excess thickness. The latter has a maximum magnitude of 200-250 m, so that the compaction correction does not eliminate the 'as measured' excess thickness of the post-LC rim syncline. Further calculations indicate that excess thicknesses persist through the entire UC and Danian chalk intervals, so that Mors did undergo extended, slow post-diapirism.

Neglecting compactional effects, the post-burial history of diapirs has been inferred in several studies[7,12] on the basis of

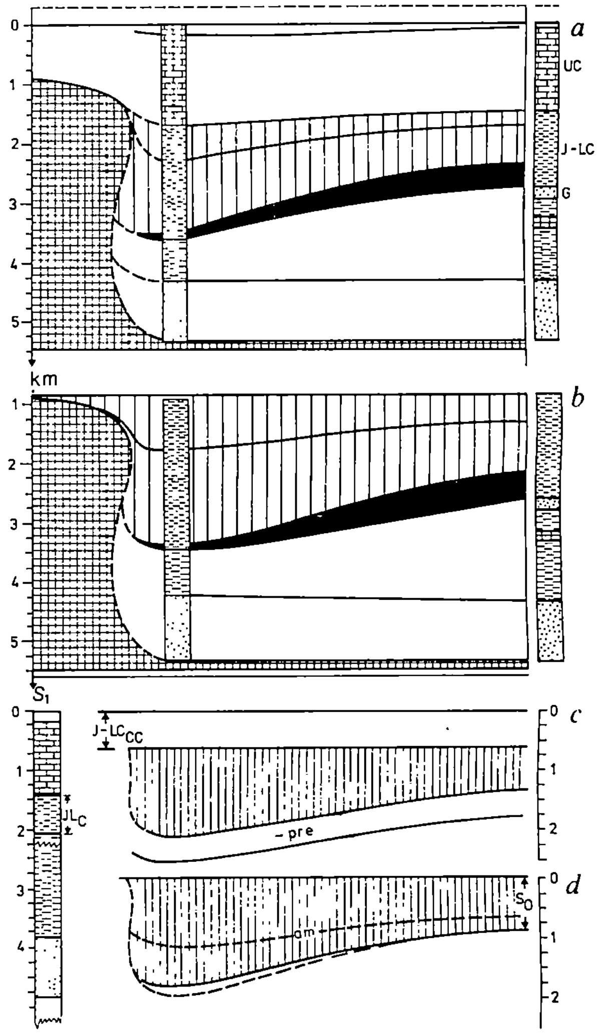

Fig. 6 Depletion history along 7908 and the total excess rim syncline. *a*, Present configuration. Black, the primary rim syncline. The lower boundary to the primary rim syncline corresponds to line au of Fig. 5. Vertical ruling, the secondary rim syncline. The lower boundary to the secondary rim syncline corresponds to reflector x of Fig. 5. White above ruling: the tertiary rim syncline. UC, Upper Cretaceous. J-LC, Jurassic and Lower Cretaceous. G, Gassum Formation. The upper stippled line indicates the maximum possible post-Oligocene erosion. Lithology symbols as in Fig. 5. *b*, End Lower Cretaceous configuration. Decompaction has been performed assuming an exponential decay of porosity (f) with depth (z), $f=f_0\exp(-cz)$, where $1/c$ is the depth constant, the depth at which the porosity has decreased to $1/e$ of its original value), and the following material parameters[11]: sandstone ($c=0.27$; $f_0=0.49$), sandy shale ($c=0.39$; $f_0=0.56$), shale ($c=0.51$; $f_0=0.63$). Measuring z in km, c is in units of km^{-1}. *c*, Primary and secondary rim syncline (vertical ruling) after subtraction of a compaction-corrected Jurassic–Lower Cretaceous thickness (J-LC$_{cc}$) derived from J-LC of Skive 1(S1) and after subtraction of the pre-correction (-pre). Skive 1 was terminated at a depth of 2,300 m below sea level; the Skive 1 column below this level was derived by a depth conversion of reflection data[14]. *d*, The compaction-corrected excess rim syncline (between zero level and the lower stippled line). Vertical ruling: the pre-UC part of the excess rim syncline. The excess thickness derived from uncorrected data: between zero level and am. All depth scales in km below sea level.

thickness differences between layers above and outside the diapir. The very large expansion of the pre-UC sections after removal of the post-Lower Cretaceous (LC) section at Mors shows that neglect of compactional effects in this procedure will lead to completely false conclusions as to post-burial rise rates. At Mors, this procedure[13] would indicate a post-LC rise of 700 m, to which should be added an unknown height equivalent of dissolved salt. The excess volume shows that the true post-LC rise of the diapir at a maximum (with no dissolution) could have been ~100 m.

Mors total excess volume

The volume estimation leading to equation (9) will now be applied to profile 7908 in order to derive the total excess volume along it. The reflection profile (Fig. 5) shows a pronounced on-lap sequence of Gassum and lower Fjerritslev formation times. This angular unconformity ('au', Fig. 5) suggests fast pillow growth, similar to the model of Fig. 2*b*. There are only slight indications of pre-Gassum time salt depletion along 7908, so that au can be taken as the lower boundary to the primary rim syncline (Fig. 6*a*). In the preceding discussion of volume, the choice of a pillow phase growth model (Fig. 2*a*) was 'justified' by analogy with experimental work[8]. The on-lap sequence above the angular unconformity au (Fig. 5) shows that this choice is realistic in the case of Mors. The occurrence of similar on-lap structures adjacent to other salt structures in the Danish basin suggests a wider applicability of this pillow growth model.

Reflector x of Fig. 5 has been chosen to represent the pillow to diapir transition of Mors. When allowing for compactional effects, an abrupt change to excess thicknesses adjacent to the diapir takes place at approximately this level (corresponding to mid-Lower Jurassic time). The post-diapiric, diapiric, pillow and pre-pillow phases of the basin north of Mors can now be delineated (Fig. 6*a*), acknowledging that the diapiric to post-diapiric transition is arbitrarily positioned at the LC–UC transition.

The geometry of the 'total' rim syncline (encompassing the total structure development), except for minor post-LC movements, is shown in its positively post-corrected form in Fig. 6*b*. The negative pre-correction is calculated by decompaction to the lower boundary of the total rim syncline, giving the corrected, total rim syncline (Fig. 6*c*). The total excess volume can now be derived by subtraction of the regional normal. The original source layer thickness, s_0, will then appear as the minimum height of the excess rim syncline. The crucial point of this process is the derivation of the 'regional normal', because this thickness exists nowhere near Mors. The choice of the 'regional normal' will be explained below.

A comparison of seismic sections over the Rødding Flat (Fig. 4) and sections crossing the Skive 1 well and the Skive structure indicates that the J-LC of Skive 1 is similar to the J-LC of the Rødding Flat west of the Skive pillow structure where no J-LC salt movement occurred[14]. The J-LC thickness in Skive, being 549 m, can therefore be used as the 'regional normal'. To find the total excess thickness, the compaction-corrected regional normal (J-LC_{cc}, Fig. 6*c*) is subtracted from the 'top' of the total rim syncline, while the negative pre-correction is subtracted from the 'bottom'. Subsequently, the remaining part of the rim syncline (Fig. 6*c*, ruled) is decompacted to give the compaction-corrected excess thickness (Fig. 6*d*, ruled). The lower stippled line of Fig. 6*d* shows the thickness to be added due to post-diapiric movements. This gives a source layer depletion of 850 ± 50 m (s_0 of Fig. 6*d*). Adding to this the remaining Zechstein thickness (probably a basal carbonatic and sulphatic facies, 250 ± 50 m thick) yields an original Zechstein thickness (z_0) of 1,100 ± 100 m.

The total excess volume is clearly as much as 50% larger than the total salt volume (allowing for three-dimensional effects[15]), illustrating the significance of the overlap volumes (equation (9) and Figs 2*a*, 3*a*) in the volume estimation. Following Trusheim, this would lead to erroneous conclusions about the amount of dissolved salt. It is also seen (Fig. 6*d*) that the true excess volume is considerably larger (again ~50%) than the 'as measured' excess volume.

Conclusions and implications

The discussion of volume estimation for salt diapirism leads to the conclusion that the total excess volume cannot be simply related to the amount of salt as claimed by Trusheim's[1] volume rule. It is necessary to account for the interrelation of several volume terms—surface sink and source volumes, subsurface displacement volumes and overlap volumes—and to relate these to the excess volume, taking into account the fact that the latter can vary with varying rates of regional sedimentation.

For the discussion of the disposal of high-level waste in salt structures, it is essential to have maximum confidence in both growth histories and growth rates. The example of Mors shows that this goal can only be reached by the use of rigorous volume estimation, for without it, diapiric rise rates may be considerably underestimated (Fig. 6*d*). The discussion of the post-burial history of Mors shows, on the other hand, that it is possible to document very long periods of vanishingly small post-diapiric movement, a period whose growth rate in previous studies has been grossly overestimated due to the neglect of compactional effects.

The discussion of volume estimation is of relevance to another applied aspect of salt structures, petroleum exploration. In this context, sink and source volume relations should be emphasized. In the 'dissolution mode' of diapiric movement the diapir itself does not provide a source to fill the sink volume. In this mode, accumulation of source material for petroleum generation may be enhanced in the sink, in contrast to the diapiric periods without dissolution.

Finally, to perform trustworthy analyses of tectonic subsidence histories of sedimentary basins containing salt structures, it is essential to allow for salt-induced thickness variations. In recent studies[11,16,17] of North Sea subsidence, salt-induced sedimentation has been neglected, despite the fact that many exploration wells have been located on strongly salt-influenced structures. This aspect is exemplified in ref. 18.

I thank I. Madirazza for helpful discussions at all stages of this work, and L. Jans and E. M. Nielsen for assistance with figures and manuscript.

Direct evidence for chromosomal inversion during T-cell receptor β-gene rearrangements

A germline T-cell receptor variable region (V_β) *gene segment* ($V_\beta 14$) *has been mapped 10 kilobases to the 3′ side of the constant region* ($C_\beta 2$) *gene. The* $V_\beta 14$ *gene segment is in an inverted transcriptional polarity relative to the diversity-region* (D_β) *and joining-region* (J_β) *gene segments and the* C_β *genes. Analyses of a T-cell clone (J6.19), which has productively rearranged the* $V_\beta 14$ *gene segment, indicate that the productive* V_β–D_β–J_β *rearrangement and its reciprocal flank recombination product are linked and located at either border of a chromosomal inversion. These data demonstrate for the first time a linkage between mammalian V and C genes and verify that a functional T-cell receptor* V_β *gene can be constructed through a chromosomal inversion.*

T-CELL antigen receptors are disulphide-linked heterodimers constituted of two chains designated α and β (refs 1–3), each divided into variable (V) and constant (C) regions[4]. The T-cell receptor V_β region is encoded by three distinct sets of DNA segments designated variable (V_β), diversity (D_β) and joining (J_β)[5-9] which join during T-cell differentiation to generate a complete V_β gene[5]. The β-gene family contains two closely linked constant-region (C_β) genes denoted $C_\beta 1$ and $C_\beta 2$, each of which is preceded by a cluster of six functional joining-region (J_β) gene segments[5-7], at least one diversity-region (D_β) gene segment[8,9] and an unknown number of V_β gene segments.

Before somatic rearrangements, the 3′ side of the V_β gene segments, the 5′ side of the J_β gene segments and both sides of the D_β gene segments are flanked by recognition sequences for DNA rearrangement. These recombination signal sequences are comprised of three components—a conserved heptamer, a non-conserved spacer sequence of 12 or 23 nucleotides and a conserved A+T-rich nonamer[5-9]. As in immunoglobulin genes, DNA rearrangement occurs only when one gene segment has a 12-base-pair (bp) recognition sequence and the second has a 23-nucleotide signal sequence.

Several mechanisms have been suggested for the joining process[10,11]. First, the DNA between the two gene segments may loop out and be deleted by virtue of a site-specific recombination event joining the two gene segments (looping out-excision model)[12,13]. Second, during mitotic duplication of a chromosome, an unequal crossing-over may occur between the 3′ end of a gene segment on one sister chromatid and the 5′ end of the second gene segment on the second sister chromatid. The two resulting chromatids would be segregated at the next cell division, giving rise to two types of daughter cells. One cell would contain the joined gene segments; this cell and its progeny would appear to have deleted all the DNA between the recombined gene segments. The second cell would contain a reciprocal flank recombination product with the two recombination signals fused back-to-back at their coding-proximal borders. This model is denoted unequal sister chromatid exchange[14,15]. A third model, particularly relevant to the data presented in this article, requires that the two gene segments to be joined are oriented in opposite transcriptional polarity in the germline DNA. Inversion of the stretch of chromosomal DNA between the 3′ (or the 5′) ends of these two gene segments would result in the formation of (1) an appropriate coding joint with both gene segments in the same transcriptional direction and (2) a reciprocal flank recombination joint. This inversion model does not lead to the loss or gain of intervening sequences between the joined gene segments but merely to their rearrangement[15-18]. Finally, the looping out-excision model may have an alternative form in which the excised loop is reintegrated back into the genomic (looping out-excision-reintegration model)[19,20]. However, since recombination events may occur in several steps during ontogeny[17,21-24], a combination of inversion or sister chromatid

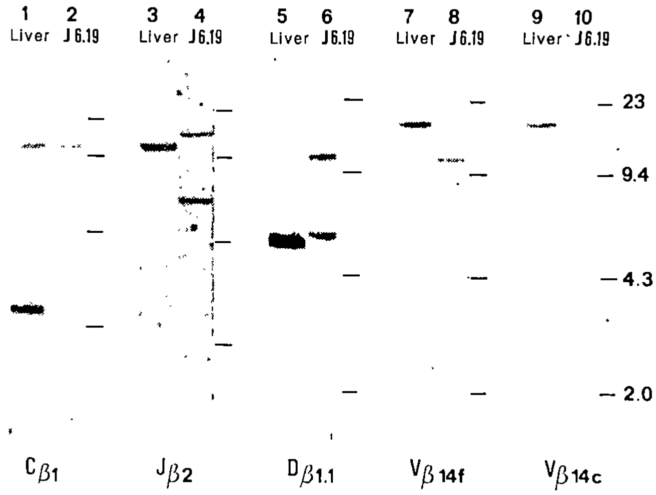

Fig. 1 Southern blot analyses of J6.19 T-cell DNA. DNAs from B10.A liver and J6.19 T cells were digested to completion with *Eco*RI (lanes 1, 2) or *Bam*HI (lanes 3–10) and after gel electrophoresis and transfer, hybridized to ^{32}P-labelled single copy probes. Probes were isolated from either the germline β-chain gene cosmid 2.3W7 (ref. 6) or the λ genomic clones 47.1 J6.19 and 46.1 J6.19 (this paper). The $C_\beta 1$ probe is a 2.5-kb *Eco*RI fragment that hybridizes to $C_\beta 1$ as well as to $C_\beta 2$ sequences because of homology between these two genes. Probe $J_\beta 2$ is a 2.3-kb *Eco*RI fragment which contains all of the $J_\beta 2$ gene segments. Probe $D_\beta 1.1$ is a 3.2-kb *Hin*dIII-*Bam*HI fragment which detects sequences 5′ to $D_\beta 1.1$, the $D_\beta 1.1$ and the two 5′ $J_\beta 1$ gene segments. Two probes were used to analyse the $V_\beta 14$ gene segment. The first one, denoted $V_\beta 14$c, corresponds to a 250-bp *Mbo*II fragment contained entirely within the $V_\beta 14$ coding sequence. The second probe, denoted $V_\beta 14$f, is a 4-kb *Eco*RI-*Sal*I fragment corresponding to the non-coding 3′ side of the $V_\beta 14$ gene segment. The parental B10.A strain liver DNA is included in each analysis for comparison of the rearrangements with the germline pattern. Size markers are indicated in kb.

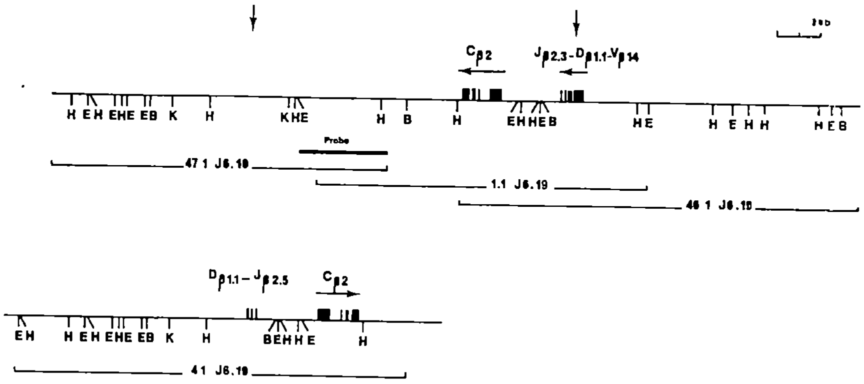

Fig. 2 Restriction maps of the genomic clones containing the β-gene rearrangements observed in J6.19 T lymphocytes. Exons encoding V_β, D_β and J_β gene segments and C_β genes are indicated by vertical lines or boxes above the horizontal line. Cleavage sites are indicated by vertical lines below the horizontal line. Restriction enzyme abbreviations are as follows: B, *Bam*HI; E, *Eco*RI; H, *Hin*dIII; K, *Kpn*I. A genomic library was constructed from *Sau*3A partially digested J6.19 DNA using the λ bacteriophage vector EMBL-3 (ref. 41). Screening of the library was carried out according to Maniatis *et al.*[42] using probes specific for D_β 1.1, C_β1, J_β2 and C_β2 sequences (see below). DNA was prepared from the isolated genomic clones and mapped with the restriction enzymes indicated. The location of the V_β, D_β, J_β and C_β sequences was determined by Southern blot analyses of restriction fragments from the genomic clones. Some hybridization probes have been described previously; they correspond either to subclones made from the germline β cosmid 2.3W7[6,11] or to oligonucleotides specific (1) for each of the 12 functional J_β gene segments, (2) for the 5'-flanking sequences of the D_β1.1 and D_β2.1 gene segments and (3) for the D_β1.1 and D_β2.1 gene segments[27,35]. The restriction fragments contained in these clones account for all the rearrangements detected in the Southern blot analysis of KB5-C20 DNA (see Fig. 1). The position of the 4-kb *Eco*RI-*Sal*I fragment isolated from clone 47.1 J6.19 and used to probe the J6.19 genomic library is indicated by a filled box. Vertical arrows indicate the border of the chromosomal inversion. Horizontal arrows indicate 5' to 3' orientation.

exchange and deletion can explain all existing observations[11,17,25].

We report here the molecular linkage of a germline T-cell receptor V_β gene segment 3' to the C_β locus. This V_β gene segment (V_β14) is oriented in opposite transcriptional polarity relative to the D_β and J_β gene segments and the C_β genes. Analyses by chromosomal walking techniques of a T-cell clone that has productively rearranged the V_β14 gene segment demonstrate that the productive V_β-D_β-J_β rearrangement and its reciprocal flank recombination product are linked on the same piece of DNA and located at either border of a chromosomal inversion. Taken together, these data represent to our knowledge the first formal demonstration of a chromosomal inversion mechanism operating during V_β to D_β-J_β joining.

β-Gene rearrangements in T cell J6.19

J6.19 is a proliferative T-cell clone that originates from a B10.A mouse and responds to hen egg ovalbumin presented by I-A^k-bearing cells[26]. DNA from J6.19 cells was digested with *Eco*RI and *Bam*HI and Southern blots of the digested DNA were then hybridized with the probes described in Fig. 1. Hybridization of the C_β1 probe to *Eco*RI-digested B10.A liver DNA shows the C_β1 (lower band) and C_β2 (upper band) genes in their germline configurations. *Eco*RI digests of J6.19 DNA hybridized to the C_β1 probe demonstrate that both C_β1 genes are deleted and that at least one C_β2 gene is present. Hybridization with the J_β2 probe shows that the J_β2 cluster is rearranged on both chromosomes of J6.19 T cells. Finally, hybridization with the D_β1.1-J_β1.1-J_β1.2 probe indicates that this region is twice rearranged in J6.19 cells.

To further delineate the nature of the β-gene rearrangements in J6.19 T cells, we have constructed a complete λ phase genomic library and isolated the clones encompassing all of the β-gene rearrangements observed during Southern blot analyses. Three classes of clones were found for J6.19 DNA, represented by clones 4.1, 46.1 and 47.1 (Fig. 2). The localization within the clones of the D_β and J_β gene segments and the C_β genes was determined using the hybridization probes described in Fig. 2 legend. Clone 46.1 has no C_β1 gene. Oligonucleotide probes show that the D_β1.1 gene segment is joined to the J_β2.3 gene segment and that the 5'-flanking sequence for the D_β1.1 gene segment is absent—therefore, this clone contains a V_β-D_β1.1-J_β2.3 rearrangement. Clone 4.1 has a D_β1.1 gene segment joint to a J_β2.5 gene segment and does contain 5'-flanking sequence for the D_β1.1 gene segment—therefore, this clone encodes a partial D_β1.1-J_β2.5 rearrangement. Clone 47.1 is novel in that it contains the rearranged 5'-flanking D_β1.1 sequence and does not hybridize to the J_β or C_β probes. A vertical arrow indicates the localization of the 5'-flanking D_β1.1 sequence inside clone 47.1 (Fig. 2). This clone will be discussed later as it has important implications for β-gene rearrangement mechanisms. These three β-gene rearrangements represent all of those observed by Southern blot analyses in the J6.19 T cells (Fig. 1).

The complete variable gene and novel rearrangements have been subcloned and sequenced (Fig. 3). The V_β rearrangement in λ clone 46.1 appears functional in that it has appropriate leader and V_β gene segment sequences and a V_β-D_β-J_β joining that maintains the proper translational reading frame (Fig. 3). The sequence of the V_β gene segment from clone 46.1 of the J6.19 cells is reported here for the first time. This V_β segment detects a single hybridizing band when used to probe a Southern blot of B10.1 liver DNA (Fig. 1) and, accordingly, defines a new single-member V_β subfamily. According to the nomenclature introduced by Barth *et al.*[27] and Kronenberg *et al.*[10], this V_β gene segment will be denoted V_β14.

The novel rearrangement observed in clone 47.1 corresponds to a flank recombination product with the heptamer sequences of V_β and D_β rearrangement signals joined in a back-to-back orientation (Fig. 3). Similar rearrangements have been reported for some immunoglobulin genes[14–20]. Does the flank recombination product of clone 47.1 correspond to the reciprocal of the V_β-D_β rearrangement defined by clone 46.1? If so, 5' D_β1.1 recognition sequences for DNA rearrangement should be joined to the 3' V_β14 recognition sequences. To answer this question we have isolated (see below) and determined the nucleotide sequence of the germline V_β14 gene segment (Fig. 3). Comparison of the coding sequences of the germline V_β14 gene segment and its rearranged counterpart found in J6.19 T cells demonstrates no nucleotide differences and further illustrates the lack of somatic hypermutation in T-cell receptor β genes. Moreover, comparison of the 3'-flanking sequence of the germline V_β14 gene segment and of the V_β recognition sequence of the V_β-D_β flank recombination product found in J6.19 T cells demonstrates a complete nucleotide identity (Fig. 3). Therefore, these data indicate that the V_β14 gene segment rearranged in J6.19 T cells has not segregated away from its reciprocal flank recombination product. Since the sister chromatid exchange model requires that the reciprocal events segregate independently in the two daughter cells, the β-gene rearrangement data obtained with J6.19 T cells are only consistent with either an inversion model or with the looping out-excision-reintegration model.

```

Fig. 3 Sequencing strategies (*a*) and sequences (*b*) of the $V_\beta 14$ germline segment, the $V_\beta 14$–J6.19 coding joint and the 47.1–J6.19 reciprocal flanking joint. The sequence of the $V_\beta 14$ germline segment denoted $V_\beta 14$ GL was obtained from a 5-kb *Eco*RI fragment derived from cosmid 40.1 W7 (see Fig. 4). The $V_\beta 14$–$J6.19$ sequence corresponds to the rearranged $V_\beta 14$ gene segment found in J6.19 T cells. The sequence denoted 47.1–J6.19 corresponds to the $V_\beta 14$–$D_\beta 1.1$ flank recombination product found in J6.19 T cells. This latter sequence was obtained from a 300-bp *Acc*I fragment hybridizing to a $D_\beta 1.1$ flanking oligonucleotide probe. *a*, The sequences were obtained by either the dideoxy-chain termination methods (wavy arrows) or by the procedure of Maxam and Gilbert. Closed circles indicate a 5′ end labelling and open circles a 3′-end labelling. The following abbreviations are used: L, leader; V_β, variable gene segment. The restriction enzyme abbreviations are as follows: A, *Acc*I; E, *Eco*RI; G, *Bgl*I; H, *Hin*dIII; Hh, *Hha*I; K, *Kpn*I; M, *Mbo*II. *b*, Comparison of the $V_\beta 14$ GL nucleotide sequence with the $V_\beta 14$-J6.19 and 47.1–J6.19 sequences. The predicted amino-acid sequence encoded by the $V_\beta 14$ exons is indicated above using the one-letter amino-acid code. Nucleotide identities with the upper line are shown with dashes. The D_β and V_β recognition sequences have been boxed. Note that the 3′ side of the germline $V_\beta 14$ gene segment is flanked by the sequence CACACTG-(23 nucleotides)-GCAAAAACC which is similar to the recognition signals found 3′ to the immunoglobulin *V* region genes[10].

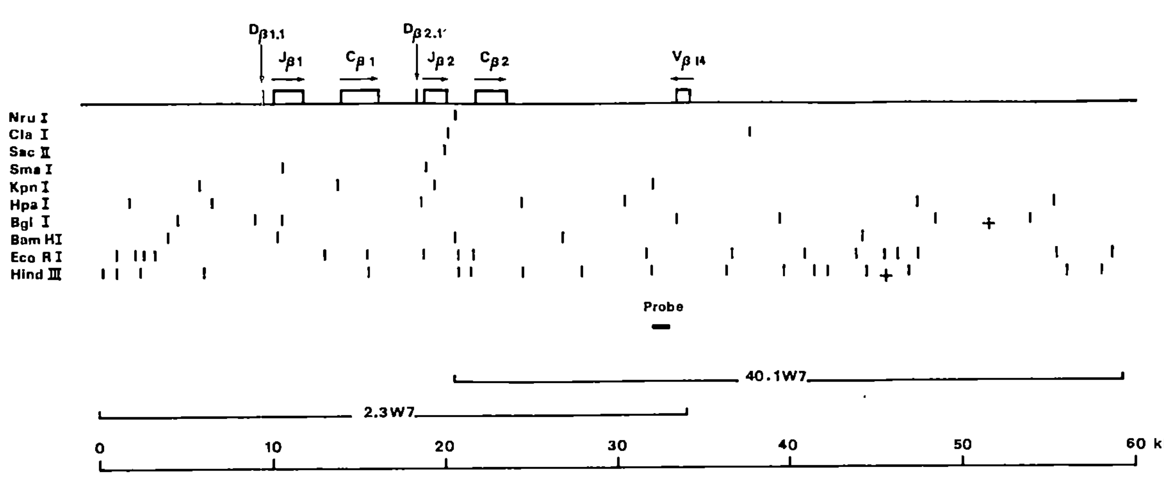

Fig. 4 Restriction map of the clones 2.3W7 and 40.1W7 isolated from a cosmid library constructed with DNA from the livers of B10.WR7 mice. Boxes or vertical lines above the horizontal line indicate the exons encoding V_β, D_β, J_β and C_β sequences. The cosmid clone 2.3W7 has been described previously[6]. The position of the 900-bp *Kpn*I-*Sau*3A probe used to isolate the cosmid 40.1W7 is indicated by a filled box. The cosmid clone 40.1W7 was mapped with the restriction enzymes indicated by single and double digestions. A (+) between two restriction sites indicates the presence of unassigned sites in this region for the same enzyme. The orientation and the location of the different gene segments were determined by Southern blot analyses of restriction fragments. The hybridization probes are described in the legend to Fig. 2. Arrows indicate 5′ to 3′ transcriptional orientation.

V_β14 gene segment lies 10 kb 3′ to C_β2

Further clues concerning the location of the V_β14 gene segment were unexpectedly obtained during analysis of the KB5-C20 alloreactive cytotoxic T-cell clone generated from a B10.BR mouse and directed against the H-2K^b molecule[28]. KB5-C20 T cells present two incomplete D_β–J_β rearrangements on one chromosome and a complete V_β–D_β–J_β rearrangement on the second chromosome (data not shown). In order to determine whether the V_β gene segment used in KB5-C20 T cells had been reported previously, the λ genomic clone corresponding to a complete V_β–D_β–J_β rearrangement (clone 28.1 KB5) was hybridized with a panel of probes specific for various V_β gene segments. Unexpectedly, clone 28.1 KB5 hybridized with two different V_β probes corresponding to V_β (refs 27, 29) and V_β14 (this paper). These two V_β gene segments show less than 20% homology. We have subsequently determined the relative positions of the V_β2 and V_β14 gene segments within the 28.1 KB5 clone. The V_β2 gene segment mapped to the 5′ side of the J_β2–C_β2 sequences. Surprisingly, the V_β14 gene segment mapped about 10 kilobases (kb) to the 3′ side of the C_β2 gene. However, T lymphocytes undergo complex β-gene rearrangements during T-cell differentiation[11] and these may have brought the V_β14 gene segment to its position in clone 28.1 KB5. We have therefore analysed the germline localization of the V_β14 gene segment before any β-gene rearrangement.

We have described previously a 34-kb mouse cosmid clone denoted 2.3W7 containing the C_β1 and C_β2 genes with their associated D_β and J_β gene segments[6]. This clone was isolated from a cosmid genomic library constructed from B10.WR7 liver DNA. We have now extended the molecular map to the 3′ side of the C_β2 gene by chromosomal walking. The single-copy probe used for that purpose corresponds to a 900-bp *Kpn*I-*Sau*3A fragment derived from the 3′ end of the cosmid clone 2.3W7 (Fig. 4). This procedure yielded the cosmid clone 401.1 W7 and allowed us to extend our map about 35 kb to the 3′ side of the C_β2 gene (Fig. 4). Southern blots of the 40.1 W7 cosmid clone were then hybridized with the V_β14 gene segment probe. This probe was found to hybridize strongly to a 5-kb *Eco*RI fragment located to the 3′ side of the C_β2 gene. Direct confirmation that this 5-kb *Eco*RI fragment does indeed encode the V_β14 gene segment was provided by DNA sequence analysis (see above). Interestingly, the germline V_β14 gene segment has a 5′ to 3′ transcriptional orientation that is opposite to that found for the D_β and J_β gene segments and the C_β genes (Fig. 4). Thus, these results demonstrate that in germline DNA the V_β14 gene segment lies 10 kb to the 3′ side of the C_β2 gene and is oriented in opposite transcriptional polarity relative to the D_β and J_β gene segments and the C_β genes.

V_β14 rearrangement by chromosomal inversion

The V_β14 gene segment constitutes to our knowledge the first example in which a germline V_β segment has been linked to the locus encoding the D_β and J_β gene segments and the C_β genes. Therefore, further analysis of the DNA rearrangements accompanying the productive V_β14 joining event observed in J6.19 T cells has provided additional insights into the mechanism of V_β to D_β–J_β joining. Because the germline V_β14 segment is oriented in an opposite polarity relative to the D_β and J_β gene segments and the C_β genes, one way to interpret the reciprocal recombination products found in J6.19 T cells involves a chromosomal inversion event. As outlined in Fig. 5, if the V_β14 gene segment joins to the D_β1.1–J_β2.3 segment by chromosomal inversion, the reciprocal flank recombination product would be formed and retained on the same chromosome bearing the productive V_β14–D_β–J_β rearrangement. Furthermore, because we have shown that the V_β14 gene segment is located about 10 kb to the 3′ side of the C_β2 gene, the reciprocal flank recombination product should be found about 10 kb to the 3′ side of the C_β2 gene. To test this supposition, we attempted to link the genomic clone encompassing the V_β14–D_β1.1–J_β2.3 rearrangement (clone 46.1 J6.19, Fig. 2) to the V_β–D_β1.1 flank recombination product (clone 47.1 J6.19, Fig. 2). For that purpose we rescreened a complete λ genomic library made from J6.19 T cells using a single-copy probe derived from the genomic clone 47.1 J6.19 (Fig. 2) and isolated one clone, denoted 1.1 J6.19. Subsequent mapping with restriction enzymes and Southern blot analyses of restriction fragments established that the 1.1 J6.19 clone does indeed overlap with the 46.1 J6.19 and 47.1 J6.19 genomic clones (Fig. 2). Therefore, we conclude that the V_β14–D_β1.1–J_β2.3 rearrangement and its reciprocal flank recombination product are linked on the same piece of DNA and located at either border of a chromosomal inversion. It was possible to determine the extent of the inversion region by comparing the restriction map shown in Fig. 2 with the one corresponding to the germline configuration (Fig. 4). Moreover, as predicted by the inverted joining model depicted in Fig. 5, the reciprocal flank recombination product is indeed located 10 kb to the 3′ side of the C_β2 gene. Integrity of the molecular map presented in Fig. 2 was confirmed by Southern blot analyses of J6.19 T-cell DNA cleaved with *Bam*HI and hybridized with four single-copy probes encompassing the inversion (Fig. 1). This analysis also indicates that the V_β14 segment located on the homologous chromosome lies in the germline configuration 10 kb to the 3′

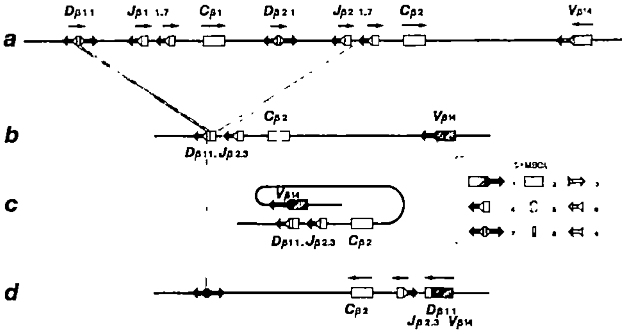

Fig. 5 Model explaining the presence in J6.19 T cells of the productive V_β–D_β–J_β rearrangement and of its reciprocal recombination product at either border of a chromosomal inversion. The chromosomal structures depicted in *a* and *d* are based on the data presented in Figs 4 and 2, respectively. Intermediate structures generated during the proposed pathway of rearrangement are illustrated in *b* and *c*. *a*, Organization of the germline C_β1 and C_β2 genes with their associated D_β (D_β1.1 and D_β1.2) and J_β (J_β1.1-7 and J_β2.1-7) gene segments. The germline V_β14 segment lies 10 kb to the 3′ side of the C_β2 gene and is oriented in opposite transcriptional polarity relative to the D_β, J_β and C_β sequences. Two stepwise recombinations must have occurred to form the final structure. *b*, An initial D_β1.1–J_β2.3 rearrangement occurred on the chromosome. This scheme is consistent with recent data suggesting that D_β to J_β rearrangements occur prior to V_β to $D_\beta J_\beta$ rearrangements (ref. 24 and R. Haars, M. Kronenberg and L.H., in preparation). The absence of both J_β1 clusters and both C_β1 genes in J6.19 T cells supports the concept that D_β to J_β rearrangement occurs either by the looping out–excision or by the sister chromatid exchange model. *c*, The V_β14 segment is recombined with the D_β1.1–J_β2.3 segment much as in the model of inverted joining hypothesized in refs 16, 18 and 25. During this process the V_β14 gene segment uses its 3′ recognition sequence to mediate joining with the D_β1.1 segment. *d*, The resulting product would have kept the entire DNA stretch located between the recombination points. A productive V_β14–D_β1.1–J_β2.3 joining would be formed with segments in the same transcriptional polarity. The reciprocal flank recombination product is also formed and lies 10 kb to the 3′ side of the C_β2 gene. The homologous chromosome is not shown; it presents a partial D_β1.1–J_β2.5 rearrangement and a V_β14 gene segment in germline configuration (see text). Arrows indicate 5′ to 3′ transcriptional orientation. Distances are not drawn to scale. Symbol for gene segments are as follows: 1, germline V_β14 segment; 2, V_β coding sequences; 3, V_β14 joining signal; 4, germline J_β segment; 5, J_β coding sequences; 6, J_β joining signal; 7, germline D_β segment; 8, D_β coding sequences and 9, D_β joining signals.

Fig. 6 Comparison of the sequences of the coding (*a*) and reciprocal (*b*) junctions located at either border of the J6.19 inversion. Heptameric elements of the joining signals are boxed; the spacer regions and nonamer elements of the joining signals are not included in the sequence shown. Nucleotide regions not accounted for by germline V_β or D_β sequences (N region) are enclosed in circles. The sites of crossing-over are shown by black triangles. The $V_\beta14$-$D_\beta1.1$-$J_\beta2.3$ reading frame is indicated by ticks above the first base of each codon. The sequences corresponding to the $V_\beta14$-$D_\beta1.1$-$J_\beta2.3$ coding joint, the $V_\beta14$-$D_\beta1.1$ reciprocal joint and the $V_\beta14$ germline segments are from this article (Fig. 3). The germline $D_\beta1.1$ segment has been reported previously[9,28].

end of the $C_\beta2$ gene. Taken together, these results demonstrate unequivocally that the $V_\beta14$ to D_β-J_β rearrangement observed in J6.19 T cells has occurred through a 14-kb chromosomal inversion.

DNA joints not precisely recombined

The 14-kb inversion observed in J6.19 T cells creates two new DNA joints. One is the V_β-D_β coding joint and the other is the reciprocal flank recombination signal joint. Analysis of the sequence of the $V_\beta14$-$D_\beta1.1$ reciprocal joint indicates that three nucleotides separate the two heptamers (Fig. 6*b*). Two of these intervening nucleotides appear to be derived from germline sequences 5′ to the $V_\beta14$ heptamer whereas the third one may originate from the 3′ side of the $D_\beta1.1$ heptamer. Thus, all three intervening bases could be accounted for by germline sequences. This observation suggests that the recognition sequences need not be precisely joined in the rearrangement process[18,25]. Such an intervening triplet of nucleotides has not been found in V_κ to J_κ reciprocal joints. In fact, in each κ example reported to date, the two heptamers are joined precisely back to back[15,18,19,23,24,30]. Unfortunately there is no way of knowing on the basis of a single example if the nucleotide triplet separating the two heptamers should be considered as a characteristic feature of the V_β-D_β reciprocal joint.

Analysis of the coding joint (Fig. 6*a*) indicates that two nucleotides have been deleted from the coding sequences of the $D_\beta1.1$ gene segment. Because the germline $D_\beta1.1$ gene segment sequence is derived from B10.A, the same strain from which J6.19 T-cell clone is derived, we may conclude that two nucleotides have been deleted from the coding sequences of the $D_\beta1.1$ gene segment. Therefore, joining does not conserve all of the sequences present in the precursor elements. Furthermore, two bases between the joined $V_\beta14$ and $D_\beta1.1$ gene segments cannot be accounted for in either germline gene segment and may represent an N region. N regions consist of short stretches of random nucleotides appearing as insertions at V-D and D-J junctions of both immunoglobulin heavy-chain[16,31-34] and T-cell receptor β genes[8,9,35]. A direct conclusion obtained from the comparison of the reciprocal recombination products and of their precursor sequences is that DNA elements are asymmetrically joined during the V_β-D_β recombination event. The reciprocal joint sequence arises entirely from the precursor germline sequences, whereas the coding joint sequence shows both an N region and a small number of base pairs missing relative to the precursor sequences. Similar conclusions have been reached during the analysis of the products formed during V_κ to J_κ joining events[18,25].

Discussion

We have mapped the germline $V_\beta14$ gene segment 10 kb to the 3′ side of the $C_\beta2$ gene and shown that it presents an inverted transcriptional polarity relative to the D_β and J_β gene segments and the C_β genes. Having examined a productive $V_\beta14$ joining event, we present evidence that V_β-D_β joining can occur via chromosomal inversion. These results have been obtained from genomic libraries constructed from B10.A, B10.BR or B10.WR7 DNA. These three strains of mice share the same chromosome 6 derived from the B10 background[36]. To extend our results to other strains of laboratory mice, we have performed Southern blot analyses of AKR, BALB/c, C3H and C57BL/6 liver DNA cleaved with seven different restriction enzymes (*Bam*HI, *Bgl*II, *Eco*RI, *Hin*dIII, *Pst*I and *Pvu*II) and hybridized these DNAs with probes $C_\beta2$, $V_\beta14$c and $V_\beta14$f (see legend to Fig. 2). In all cases the sizes of the genomic fragments correspond with those predicted by the map obtained from B10.WR7 mice. Further support for this model was obtained by the direct analysis of a β-genomic clone derived from A.TL DNA (D.B. and C.D., unpublished observations).

An analysis of the β-gene rearrangements in the T J6.19 cells suggests they occurred in the following manner. Initial $D_\beta1.1$-$J_\beta2$ rearrangements occurred on both β-locus chromosomes. This contention is consistent with recent data suggesting that D_β-J_β rearrangements occur before V_β to $D_\beta J_\beta$ rearrangements[24] (R. Haars, M. Kronenberg and L.H., in preparation). Since the $J_\beta1$ clusters and $C_\beta1$ gene have been deleted from both chromosomes in the J6.19 cells, the $D_\beta1$-$J_\beta2$ joining events must have occurred by the looping out-excision or by the sister chromatid exchange mechanisms. The chromosome 6 represented by clone 4.1 presumably did not undergo any further β rearrangement (Fig. 2). The $V\beta$ to $D_\beta J_\beta$ rearrangement on the other chromosome 6 presumably led to the V_β-D_β flank recombination products of clone 47.1, thus requiring an inversional mechanism for DNA rearrangements (Fig. 5). Indeed, the inversion model would predict that each time the $V_\beta14$ gene segment of the J6.19 cells is used, there should be a flank recombinational product present in that T cell. Thus, T cell J6.19 must use two distinct mechanisms for DNA rearrangement—one for $D_\beta J_\beta$ joining and a second for V_β to D_β-J_β joining.

We have shown that the joining signals of $V_\beta14$ and $D_\beta1.1$ have recombined, leading to an inversion of a region of the T-cell receptor β locus. Such a V_β-D_β joining could not have occurred by unequal sister chromatid exchange, because a dicentric and an acentric chromosome would have resulted from such an event. In fact, each time the $V_\beta14$ gene segment is used because of its inverted translational orientation, it should be joined by chromosomal inversion and there should be a flank recombination product present in that cell. It is interesting that in immunoglobulin genes, the reciprocal joints apparently do not accumulate at the λ or heavy-chain gene loci with the same frequency with which they are found at the κ locus[18,25]. In fact, the feasibility of an inversion model for κ-gene joining has recently been established by the *in vitro* joining experiments of Lewis *et al.*[18,25]. Because we have demonstrated that the presence of a V_β-D_β reciprocal joint is a consequence of the topological relationships between β-gene segments, we believe that in a similar way some V_κ gene segments will be found in an inverted orientation either 5′ or 3′ relative to the C_κ gene.

The T-cell receptor β-chain locus constitutes a striking example in which the gene segments to be joined have different transcriptional polarities. How many additional V_β gene segments have the same transcriptional polarity as the $V_\beta14$ gene segment? To date, a number of T cells have been examined for all of their T-cell receptor gene rearrangements. However, analyses of 15 helper T-cell clones (refs 35, 37 and J. Kobori and N.

Shastri, unpublished data) did not reveal any flank recombination products, a finding consistent only with V_β-D_β joining occurring via the looping out-excision or the sister chromatid exchange models. Therefore, we believe that most V_β gene segments will be in the same transcriptional polarity as the D_β-J_β-C_β gene clusters.

The β genes of the human T-cell receptor have been located on the long arm of chromosome 7, band q35 (refs 38, 39). Cytogenetic studies of lymphocyte cultures stimulated with T-cell mitogens and derived from patients with ataxia telangiectasia indicate increased chromosome breakage and various abnormalities of chromosomes 7 and 14. Particularly interesting is the observation[40] of a pericentric inversion of chromosome 7 with breakpoints at p13 and q35. It is tempting to speculate, in relation to our data, that this chromosome inversion mimics a normal site-specific V_β-D_β rearrangement by inverted joining. It should be noted with regard to this possibility that the t(11; 14) chromosomal translocation recently observed in two separate cases of B-cell neoplasms has involved a heavy-chain segment on chromosome 14 and a heptamer-nonamer signal-like sequence on the normal chromosome 11[40]. In a similar way, a mouse nonproductive κ rearrangement has been shown to involve the joining of a J_κ segment to a sequence unrelated to any V, which is flanked in the germ line by a recombination signal sequence resembling those found to the 3′ side of V gene segments[30]. Whether the pericentric inversion of chromosome 7 observed in ataxia telangiectasia involves the T-cell receptor β-chain locus and is mediated by a mechanism similar to the V_β-D_β inversion mechanism described in this article will require the molecular characterization of the chromosomal breakpoints.

We thank Drs J.-F. Brunet and P. Golstein for making available KB5-C20 RNA samples and C. Bellegarde-Kourilsky for typing the manuscript. Molecular structure of an aspartic proteinase zymogen, porcine pepsinogen, at 1.8 Å resolution

Michael N. G. James & Anita R. Sielecki

Medical Research Council of Canada Group in Protein Structure and Function, Department of Biochemistry, University of Alberta, Edmonton, Alberta, Canada T6G 2H7

The only well-understood mechanism of zymogen activation is that of the serine proteinases, in which proteolytic cleavage leads to conformational changes resulting in a functional active site. A different mechanism is now unveiled by the crystal structure of pepsinogen. Salt bridges that stabilize the positioning of the N-terminal proenzyme segment across the active site of pepsin are disrupted at low p*H, releasing the amino-terminal segment and thereby exposing the catalytic apparatus and the substrate-binding sites.*

THE specialized cells and tissues of eukaryotic organisms which produce proteolytic enzymes protect themselves from digestion by synthesizing inactive precursors of the active enzymes[1]. These zymogens have lengths of polypeptide that are N-terminal extensions of the active proteinases. Activation of a zymogen is commonly accomplished by limited proteolysis that removes the proenzyme segment extension. Many biologically important processes, such as the blood clotting cascade, are critically dependent upon this precursor to active enzyme conversion[2].

The zymogens of the pancreatic serine proteinases are usually activated upon cleavage by other proteolytic enzymes. For example, the removal of an N-terminal hexapeptide from trypsinogen by enterokinase or trypsin is accompanied by a conformational change that completes the formation of the primary substrate-binding cavity of trypsin[3]. In contrast, the zymogens of the gastric aspartic proteinases only require H^+ ions (pH <5.0) to initiate the activation process[4]. These pioneering observations of Herriott indicated that at pH 4.0–4.6 the formation of pepsin from the inactive precursor is autocatalytic.

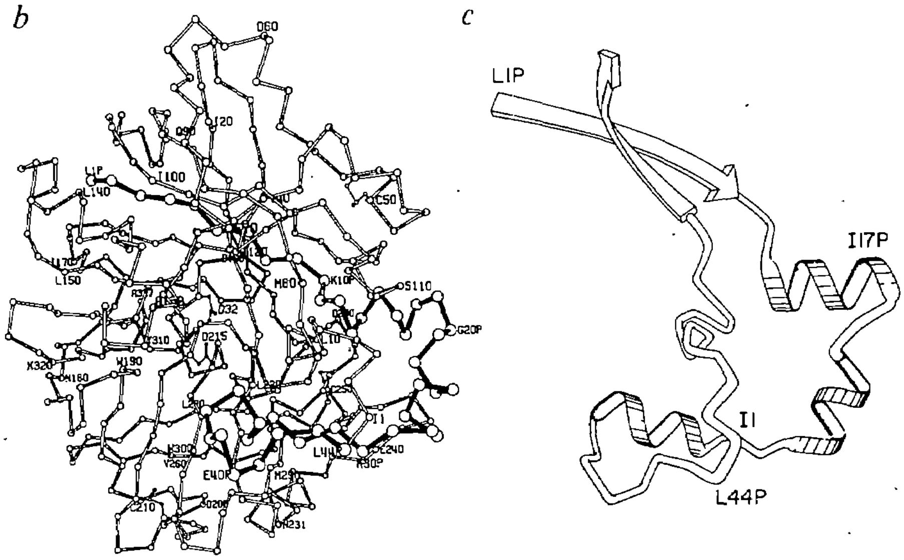

Fig. 1 ***a***, Amino-acid sequence of the proenzyme segment of pepsinogen. The 44 residues are numbered sequentially from 1 followed by the suffix P as suggested by Foltmann[13]. The residues of the active portion of the molecule are numbered according to the porcine pepsin amino-acid sequence[14,15]. ***b***, Representation of the α-carbon atom positions of porcine pepsinogen (ORTEP, C. Johnson, Oak Ridge National Laboratories). The 44 residues of the proenzyme segment have the virtual bonds that connect C^{α} atoms in thick black lines; the pepsin portion of the molecule is indicated by open bonds. The side-chain positions of Asp 32, Asp 215 and the three disulphide bridges are indicated. Every 10th residue is labelled with the single-letter code for the residue name and the sequence number. Large crystals of porcine pepsinogen suitable for high-resolution crystallographic analysis were grown by the hanging-drop, vapour-diffusion method. The protein solution contained 10 mg ml^{-1} pepsinogen (Sigma, lot 98C-0451), 1.8 M Li_2SO_4 buffered with 50 mM [*N*-morpholino]ethane sulphonic acid to a *p*H of 6.1. The crystals of the native protein are monoclinic, space group C2, with unit cell dimensions $a = 105.8$, $b = 43.4$, $c = 88.6$ Å and $\beta = 91.4°$. There are four molecules of pepsinogen, relative molecular mass ≃ 39,600, per unit cell ($V_m = 2.57$ Å^3 per dalton). The crystals used for this structure solution are similar to those of porcine pepsinogen reported previously[20] except for a 1% difference in the *a* axial length. Intensity data to 1.8 Å resolution (37,575 unique reflections) for the native pepsinogen crystals were collected on an Enraf-Nonius CAD4 diffractometer using a data collection protocol described previously[21]. The structure was solved by a combination of multiple isomorphous replacement[22] and molecular replacement[23] techniques. The molecular replacement used a search model based on the 1.8 Å resolution refined coordinates of penicillopepsin[19]. Details of this structure solution will be reported elsewhere (A.R.S., M. Fujinaga, R. J. Read and M.N.G.J., in preparation). ***c***, A ribbon drawing of the secondary structural features of the proenzyme segment (residues Leu 1P–Leu 44P of pepsinogen) along with the first 17 residues of active pepsin. Two of the scissile bonds cleaved during zymogen processing, Leu 16P–Ile 17P and Leu 44P–Ile 1, are labelled. There are three short helical stretches in the proenzyme segment, Ser 11P–Asp 19P, Lys 21P–Thr 28P, approximately orthogonal to one another, and Pro 33P–Tyr 37P. The side chains of Leu 12P, Leu 16P, Leu 22P, Phe 25P and Leu 26P contribute to the hydrophobic core of this small domain. The chain from His 29P to Asn 32P has an extended conformation. The remaining segment of the proenzyme peptide, from Pro 39P to Leu 44P, seems to have few secondary structural features. The electron density for the segment from Ala 42P to Ile 1 is relatively weak at the present refinement stage. The peptide bond between Leu 44P and Ile 1 is exposed on the surface of the molecule.

Many elegant chemical, spectrophotometric and kinetic studies have been designed to elucidate the pathway of the conversion of porcine pepsinogen to pepsin. Optical rotatory dispersion studies of pepsinogen[5] showed that the zymogen exhibits characteristics of α-helical structure not present in pepsin. Furthermore, the conformation of the zymogen is stabilized by electrostatic interactions involving the basic amino acids of the proenzyme segment and carboxylate groups on the enzyme[5]. Ultraviolet spectroscopy detects a rapid conformational change in the molecule as a solution of pepsinogen is acidified to *p*H 2.85 (ref. 6). If the *p*H of the solution is returned to neutrality after a short time, this conformational change is fully reversible and no formation of pepsin is observed; this is consistent with a possible intermediate in the reaction[6]. It has also been shown that the activation of pepsinogen in a dilute acidic solution containing an excess of substrate, haemoglobin, is independent of pepsinogen concentration, suggesting an intramolecular activation process in which the unproteolysed zymogen cleaves itself[7]. Similar deductions of a unimolecular mechanism have been made independently by Funatsu *et al.*[8,9]. Further support for an intramolecular activation comes from kinetic experiments showing that the rate of conversion of pepsinogen is a first-order reaction at *p*H values below 3, that is, independent of zymogen concentration[10]. At higher *p*H values, however, the observed kinetics are consistent with a mixed reaction mechanism in which pepsin-catalysed activation predominates[10].

The proenzyme segment of pepsinogen consists of 44 amino acids of known sequence[11,12] (Fig. 1*a*). It has not been possible to isolate the intact peptide Leu 1P–Leu 44P from activation solutions. Instead, several shorter peptides resulting from multiple proteolytic cleavages can be isolated, suggesting a sequential mechanism for the conversion. The first peptide to be observed results from the hydrolysis of the Leu 16P–Ile 17P bond, with the concomitant formation of an enzymatically active pseudopepsin molecule[16,17]. The subsequent formation of mature pepsin is concentration dependent and may represent the bimolecular component important in the activation process at relatively higher *p*H values[18].

Comparison of the crystallographic solution of the molecular structure of pepsinogen with that of an active aspartic proteinase, penicillopepsin[19], reveals the reasons for the catalytic incompetence of the intact zymogen. In addition, the observed structure (Fig. 1*b*, *c*) sheds new light on the interpretations of the many solution studies.

Molecular structure of pepsinogen

The model of pepsinogen reported here has been subjected to restrained-parameter least-squares refinement[24], following the same strategy used in this laboratory for other protein structures[25]. Whereas detailed hydrogen bonding interactions may change on further refinement and inclusion of all ordered solvent, interpretations based on the present structure should not change substantially. The high quality of the electron density

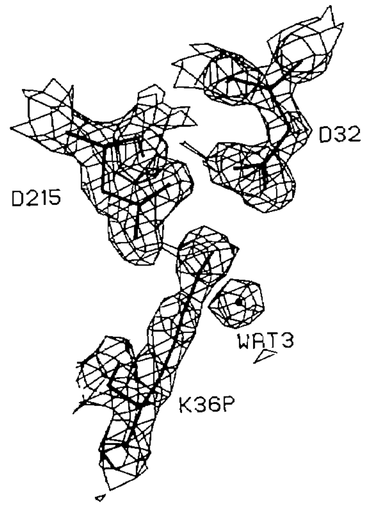

Fig. 2 Electron density contour surfaces in the vicinity of the active site of pepsinogen (Asp 32 and Asp 215). The current agreement factor between observed structure factor amplitudes, $|F_0|$, and calculated ones based on the refined atomic coordinates, $|F_c|$, is 0.167 ($R=\Sigma||F_0|-|F_c||/\Sigma|F_0|$) for the 26,191 reflections with $I \geqslant 2\sigma(I)$ in the 6.0–1.8-Å resolution range (I is the measured intensity of the reflection, $\sigma(I)$ its estimated standard deviation). The molecular model includes 110 ordered solvent molecules. The root-mean-square deviations from expected geometry are acceptably small, 0.016 Å for covalent bond lengths, 0.037 Å for bond angle-related distances, 0.025 Å for out-of-plane deviations and 4.0° for deviations from 180° for the *trans* peptide bonds. The contour level on this $2F_0-F_c$ map is 0.60 eÅ^{-3}. Full thick lines correspond to the molecular model at this stage of the refinement. Solvent molecule Wat 3 is hydrogen bonded to N^{ζ} of Lys 36P.

map at the current stage of refinement can be seen in Fig. 2. The present agreement factor is 0.167.

The crystallographic structures of four aspartic proteinases have been reported previously[19,26–28]. All four structures are highly homologous and have a general overall shape that resembles a croissant. The N-terminal domains, residues 1–170, are folded in a similar fashion to the C-terminal domains (residues ~180–327), suggesting gene duplication, divergence and subsequent fusion in the evolutionary history of these enzymes[29]. Most residues of the aspartic proteinases adopt a β-sheet conformation. The secondary and tertiary structural interactions in penicillopepsin at 1.8 Å resolution have been discussed elsewhere[19]. In all of these enzymes, the active-site aspartate residues, Asp 32 and Asp 215, are located at the junction of the two domains in an extended substrate-binding cleft. Possible modes of productive binding of substrates have been established by crystallographic studies of inhibitor binding to penicillopepsin[21,30–32] and to rhizopuspepsin[33,34].

The polypeptide chain of the pepsin portion of pepsinogen (residues Ile 1–Ala 327) folds in a fashion that is highly homologous to those of the several aspartic proteinases of known structure mentioned above. Visual comparison of the α-carbon atom chain tracing of pepsinogen (Fig. 1*b*) with that of the active pepsin molecule[28] certainly confirms this. A more detailed comparison must await the completion of the refinement of both molecular structures. Nevertheless, there is clearly a major conformational difference between the N-terminal 12 residues of pepsin and the corresponding 12 residues in pepsinogen. In pepsin, residues Ile 1–Leu 6 form strand 1 of a large six-stranded antiparallel β-sheet, a common feature of all aspartic proteinases[19]. The next five residues form a reverse turn that changes the polypeptide chain direction[28].

In contrast, these residues in pepsinogen are intimately associated with the inactivation domain, on the opposite side of the molecule (Fig. 1b). The side chain of Ile 1 in the zymogen is ~40 Å from its final position in the active enzyme. Residues Ile 1–Asp 3 are in an extended conformation, followed by a series of reverse turns from Glu 4 to Asp 11 which give the chain an irregular helical conformation. From Pro 39P to Asn 8, the polypeptide chain forms a large loop into the centre of which fits the tip of the flap (a β-hairpin loop, residues 72–82). The side chain of Leu 10 contributes to the hydrophobic core of the inactivation domain.

The overall shape of the inactivation domain of pepsinogen (residues Lys 9P–Glu 13) is that of a flattened disk with a long N-terminal extension formed by the first 8 residues, Leu 1P–Arg 8P (Fig. 1*c*). This disk-like domain fits neatly into the part of the structure that corresponds to the substrate-binding cleft in pepsin with apparently little distortion of the conformation of the active enzyme. The first six residues of pepsinogen form the first strand of the same large, centrally located six-stranded antiparallel β-sheet as do the N-termini of the active aspartic proteinases.

Mechanism of inhibition

The present molecular structure of pepsinogen clearly shows why the zymogens of the aspartyl proteinases are inactive. Part of the proenzyme segment, residues Ser 11P–Leu 44P, occupies the substrate-binding cleft of the pepsin portion of the zymogen, competitively blocking access to the two catalytically important aspartyl residues (Figs 1*b*, 2). Lys 36P has a pivotal role in the inhibition of the intact zymogen at high *p*H. This residue is in

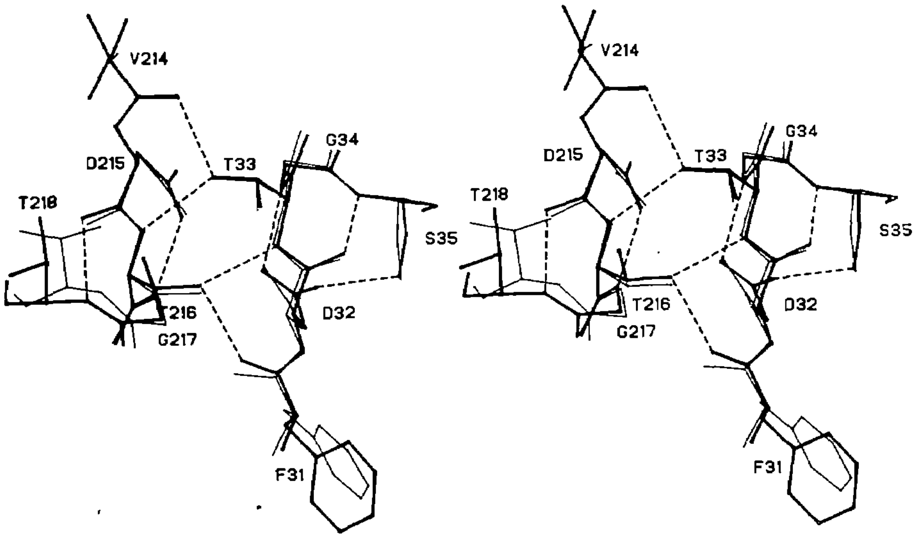

Fig. 3 A stereo representation of the two active-site strands: Phe 31–Ser 35 and Val 214–Thr 218 of pepsinogen (drawn in thick lines), superimposed on the equivalent residues of penicillopepsin[19]: Phe 32–Ser 36 and Ala 212–Thr 216 (in thin lines). Hydrogen-bonding interactions involving atoms of pepsinogen are indicated by dashed lines. The least-squares superposition of the coordinates of the main-chain atoms (N, C^{α}, C^{β}, C, O) of these residues yields a root-mean-square deviation of 0.36 Å for the 48 common atom pairs. The largest difference is associated with the main chain of Thr 218 (Thr 216 in penicillopepsin). The hydrogen bond that the $O^{\gamma 1}$ side-chain atom of this residue forms with the side-chain carboxyl group of Asp 213 in penicillopepsin has no equivalent in pepsinogen. All other hydrogen-bonding interactions for this region of the zymogen are as observed for active penicillopepsin.

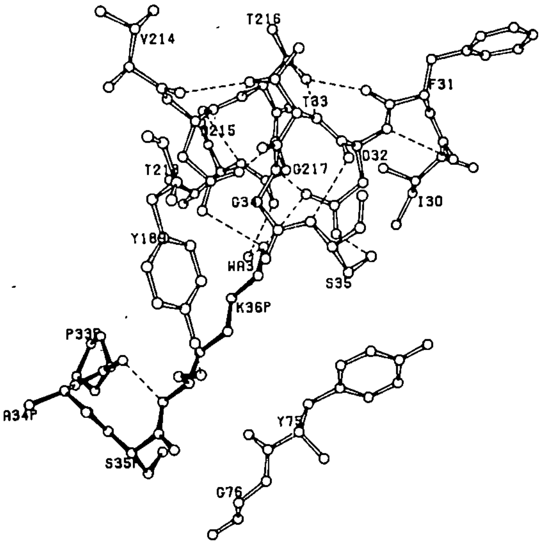

Fig. 4 A rendering of the active-site region of pepsinogen with four residues of the proenzyme segment, Pro 33P–Lys 36P (PLUTO, S. Motherwell, University Chemical Laboratory, Cambridge, UK). Hydrogen-bonding interactions are shown by dashed lines. The residues of the proenzyme segment are drawn with filled bonds, the pepsin portion with open bonds, both in this figure and in Fig. 5. The molecule labelled WA3 corresponds to water 3, depicted in Fig. 2 with its associated electron density.

a highly conserved region of the zymogens of the vertebrate aspartic proteinases[35].

We suggest that the residues of pepsinogen in the immediate vicinity of the two catalytic aspartyl residues are in, or very close to, their active conformation. It is not possible to consolidate this hypothesis by direct comparison with the known structure of pepsin[28]. Crystals of porcine pepsin have been grown from ethanol, a compound known to inhibit this enzyme. Ethanol molecules have been tentatively identified in close proximity to the aspartyl residues, a binding that could induce conformational changes[28]. In any event, only the pepsin α-carbon coordinates are available in the Brookhaven Protein Data Bank[36]. Another member of the aspartyl proteinase family, penicillopepsin, has had its crystal structure determined at its pH optimum. The details of the conformation of the active site, with its intricate hydrogen bonding, have been described elsewhere[19]. A least-squares superposition of the active-site regions of penicillopepsin and pepsinogen is depicted in Fig. 3. The small rotation of the side chain of Asp 32 relative to the native conformation of penicillopepsin, as can be seen in Fig. 3 for pepsinogen, has also been observed in the crystal structure of the complex of penicillopepsin with the inhibitor Iva-Val-Val-StaOEt (refs 21, 30).

In the active conformation of penicillopepsin, the two carboxyl groups of Asp 33 and Asp 213 are the recipients of several strong hydrogen bonding interactions[19]. Asp 32 and Asp 215 in pepsinogen have most of these hydrogen bonds present (Fig. 3) but, in addition, the positively charged N^{ζ} of Lys 36P provides electrostatic stabilization through hydrogen bonding for one of the formal net negative charges on these residues (Fig. 4). This interaction must also be an important factor in the inhibition of the inherent activity of the zymogen. It is likely that the net charge at the active site of pepsinogen is −2, as the pH of the crystals is 6.1 and the higher pK_a of the pepsin active site is 4.7. Stabilization of the second formal negative charge must come from the other favourable hydrogen bonds and dipole interactions. The position of N^{ζ} of Lys 36P relative to the two aspartic acid side chains in pepsinogen is within 0.5 Å of the refined position of a solvent molecule, 039, in penicillopepsin. We have interpreted this solvent as a bound ammonium or hydronium ion with a possible electrophilic role in the catalytic mechanism[32]. The disposition of Lys 36P provides additional evidence that the 039 site of penicillopepsin is a favourable position for the binding of positively charged groups to aspartyl proteinases, an important yet unresolved issue in the elucidation of the mechanism of the active enzymes[19,32].

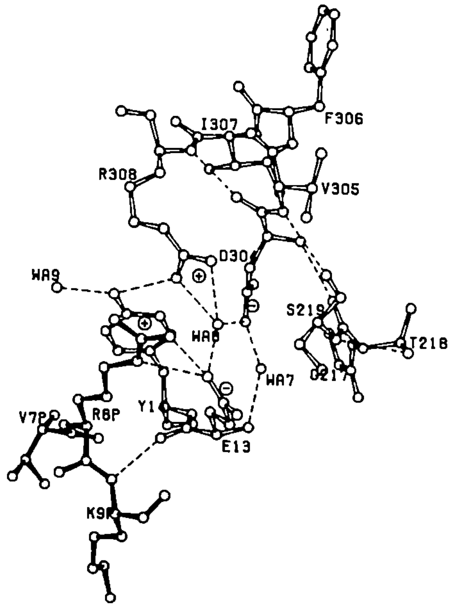

Fig. 5 The residues neighbouring the unusual interaction of Arg 8P and Arg 308 are shown (PLUTO, S. Motherwell, University Chemical Lab., Cambridge, UK). Possible hydrogen bonds are represented by dashed lines. The close proximity of the carboxylate groups of Glu 13 and Asp 304 are important in stabilizing the disposition of the two arginine residues at high pH. Protonation of Glu 13 and Asp 304 on lowering the pH below 4 would remove these stabilizing electrostatic effects and strong repulsion of the two positively charged guanidinium groups could trigger a conformational change. Water WA8 bridges the interaction between Asp 304 and Arg 308.

There are four aromatic rings in the vicinity of this electrostatic interaction of Lys 36P and the two aspartic acid carboxyl groups, Tyr 37P, Tyr 9, Tyr 75 and Tyr 189. The side chain of Tyr 75 on the flap is stacked with its aromatic plane almost perpendicular to that of Tyr 9. One of the first events detected spectrophotometrically on lowering the pH of a solution of pepsinogen from neutrality to 2–4 is an ultraviolet spectral change that can be associated with tyrosyl and tryptophan absorbance bands[6]. As the active-site carboxyl groups take up a proton, the complicated hydrogen bonding network involving Asp 32 and Asp 215 would be disrupted with a concomitant alteration in the environment of these several tyrosine side chains, as observed in the spectrophotometric experiments.

Intramolecular ionic interactions

It has been suggested that, at neutral pH, the highly positively charged proenzyme segment is bound to the pepsin portion of the molecule via ionic interactions with negatively charged carboxylate groups[5]. This early suggestion is now confirmed by the crystal structure. In addition to the ionic attractions between the Lys 36P side chain and the carboxylate groups of Asp 32 and Asp 215 that we have discussed (Fig. 4), several other electrostatic interactions contribute to this stabilization (Table 1).

A cluster of two positively charged groups (Arg 8P and Arg 308) and two negatively charged carboxylate groups (Glu 13 and Asp 304) is shown in Fig. 5. Also included in the environment of these charged groups are several highly ordered water

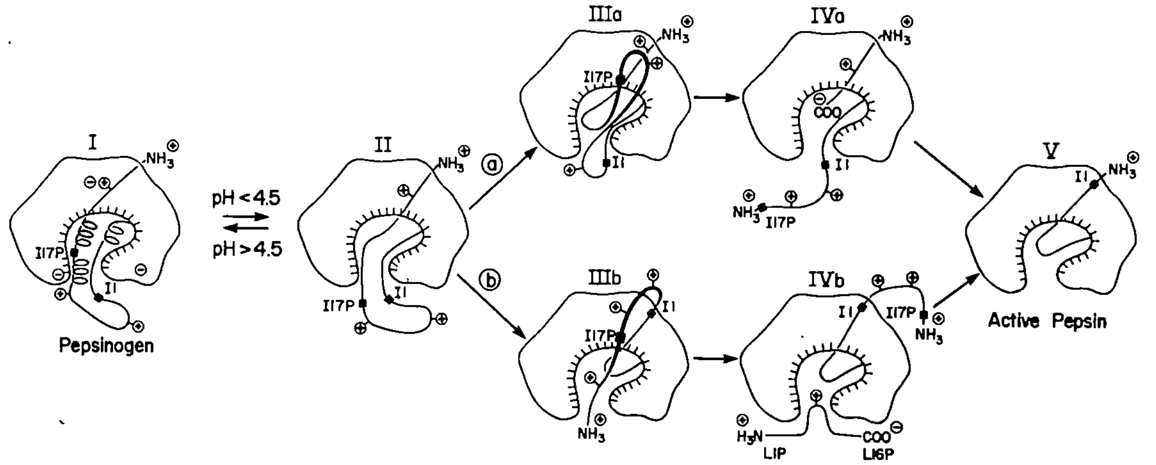

Fig. 6 Proposed steps in the activation of pepsinogen. Interconversion of structures I and II is a reversible, *p*H-dependent process. Structures III*a* and III*b* are two possible alternatives that would place the first scissile bond Leu 16P–Ile 17P at the catalytic site. In pathway *a*, the N-terminus of the zymogen remains in its crystallographically observed position; in pathway *b* the N-terminal residues of pepsin (Ile 1–Asn 8) occupy their final position by replacing the N-terminus of the proenzyme segment. The segment of polypeptide chain from Ile 17P to Ile 1 is sufficiently long to wrap around the back of the molecule, allowing the scissile bond Leu 16P–Ile 17P to approach and bind in a productive mode analogous to that shown in structure III*a*. A unimolecular reaction would release peptide Leu 1P–Leu 16P to yield structures IV*a* or IV*b*. This peptide is a known inhibitor of porcine pepsin[37] and therefore probably also inhibits pseudopepsin, as indicated schematically in structure IV*b*. Conversion of structure IV*a* or IV*b* to active pepsin probably occurs by an intermolecular pepsin cleavage to release peptide Ile 17P–Leu 44P.

molecules, WAT 7, 8 and 9, which mediate additional interactions. The positively charged guanidinium groups of the two arginine side chains stack with their planes approximately parallel, but separated by a van der Waals contact distance of ≈3.5 Å. This surprising interaction is stabilized by the close proximity of the two carboxylate groups of Glu 13 and Asp 304 (Fig. 5). A possible sequence of events on lowering the *p*H of a solution of pepsinogen is the protonation of these carboxylate groups, thus removing the charge stabilization. The two guanidinium side chains would be electrostatically repelled, inducing a changed conformation in the proenzyme segment. Similar arguments apply to protonation of the several other carboxylate groups listed in Table 1. This leads to the disruption of the conformation of the zymogen as the *p*H is lowered.

Steps in activation

The molecular structure of the zymogen of porcine pepsin places limitations on the sequence of events required to convert the inactive precursor to the activated enzyme. Structure I in Fig. 6 is a diagrammatic representation of the conformation of pepsinogen that we have determined crystallographically at $pH > 6$. On lowering the *p*H of a solution of pepsinogen, conversion of structure I to structure II (Fig. 6) is accompanied by the following known events. The carboxylate groups involved in stabilizing ion pairs (Table 1) become protonated, facilitating a conformational change in the proenzyme segment. This change can be fully reversed by raising the *p*H of the solution after a short time[6]. However, prolonged incubation results in irreversible activation with the intramolecular cleavage of the peptide bond Leu 16P–Ile 17P[16,17], a bond favoured for hydrolysis because pepsin has a specificity for hydrophobic side chains[38]. This scissile bond is part of the first helix of the proenzyme segment (Fig. 1) and residues Leu 16P and Ile 17P must move ≈18 Å to reach the active site. In addition, this bond must approach the two aspartate groups Asp 32 and Asp 215 to bind in the manner of a good substrate[31,32].

Table 1 Electrostatic interactions of the proenzyme segment with the pepsin part of pepsinogen

Positively charged residue*	Negatively charged residue	Hydrogen-bonding distances (Å)
Lys 3P ε-NH_3^+	Asp 171 COO^-	3.5
Arg 8P Guan$^+$	Glu 13 COO^-	2.9, 2.8
Arg 13P Guan$^+$	Asp 11 COO^-	2.8, 2.8
His 29P Imid$^+$	Asp 3 COO^-	2.8
His 31P Imid$^+$	Glu 7 COO^-	2.5
Lys 36P ε-NH_3^+	Asp 32 COO^-	3.0
	Asp 215 COO^-	2.8

* Guan$^+$ and Imid$^+$ stand for the guanidinium and imidazolium groups of arginine and histidine, respectively.

There are two ways in which the scissile bond Leu 16P-Ile 17P can be positioned in the substrate-binding cleft (pathways *a* and *b* of Fig. 6). Structure III*a* results when Leu 1P-Leu 6P, the extended polypeptide preceding the first helix of the proenzyme segment, remains in the zymogen conformation as part of the six-stranded antiparallel β-sheet (Fig. 1). The N-terminal to C-terminal direction of the polypeptide corresponds to that proposed for productive substrate binding to aspartyl proteinases[31–34,39]. The second mode of binding, represented by structure III*b*, occurs if the segment Leu 1P-Leu 6P is displaced by the N-terminal residues of pepsin (Ile 1-Leu 6). In both cases, intramolecularly catalysed cleavage of the bond Leu 16P-Ile 17P would yield structures IV*a* and IV*b*, respectively.

The most likely path in the conversion of intermediate structures IV*a* and IV*b* to active pepsin, structure V, is via an intermolecular cleavage step in which the peptide bond Leu 44P-Ile 1 is bound in the active site of a second activated pepsinogen (or active pepsin) molecule. These two structures, IV*a* and IV*b*, are quite analogous and are differentiated only by how peptide Leu 1P-Leu 16P is bound to the enzyme. Further degradation of the two major peptides released during the activation process takes place, resulting in many short segments[37].

The activation of mammalian aspartic proteinases from their inactive precursors is accompanied by some spectacular conformational changes. We have shown that the residues in the active site of pepsinogen are in a conformation remarkably close to the active conformation of penicillopepsin (Fig. 3). The *p*H-induced conformational upheavals involve the movement of the competitive proenzyme segment out of the active-site cleft of pepsin, exposing the catalytic apparatus and freeing the substrate-binding sites. The position of the N-terminal Ile 1 residue of active pepsin is ≃40 Å from the observed position of this residue in pepsinogen. The activation steps we propose in order to rationalize how this remarkable conformational change can take place are entirely consistent with the low *p*H unimolecular activation process that has been suggested to occur in solution.

Dr Y. Nakagawa supplied us with our initial sample of highly purified porcine pepsinogen. Koto Hayakawa has grown the pepsinogen crystals and carried out the heavy-atom search. Randy Read and Masao Fujinaga provided their expertise with the molecular replacement and phase combination methods. This research has been generously supported by the MRC of Canada in a grant to the MRC Group in Protein Structure and Function.

A radio outburst and jet from the symbiotic star CH Cyg

CH Cyg is an M7 III star that is known to undergo periods of brightening in the blue-violet continuum at irregular intervals of a few years[1–3]. During the active phase, the spectrum also exhibits strong Balmer emission and emission lines from He I, Fe II and various forbidden transitions, giving it the appearance of a symbiotic star. As part of a monitoring programme on symbiotic stars, observations with the National Radio Astronomy Observatory Very Large Array (VLA) have been made on CH Cyg over the past year at intervals of a few months. During the period April 1984 to May 1985 this monitoring revealed a strong radio outburst coincident with the production of a multi-component jet, and a comparison of high-resolution maps at two epochs separated by 75 days shows that the jet is expanding at a rate of 1.1 arc s yr^{-1}. The onset of the radio outburst coincides in time with a remarkable decline in the visual brightness of the star. The luminosity of the star during the optically active state and the energetics of the mass loss suggest that the outburst is the result of accretion at, or near, the Eddington limit onto the surface of a white dwarf.

The observations of CH Cyg trace the evolution of a radio outburst during which the flux density increased by a factor of 30. Figure 1 shows the radio light curve at $\lambda = 2$ cm. The outburst was continuing at the time of our last observation on 3 May 1985, and the radio spectrum during the outburst has remained essentially constant. Figure 2 shows radio spectra obtained at three epochs. The spectral index between 5 and 14.9 GHz is +1.2. This is typical (although slightly high) for radio-detected symbiotic stars[4], and is consistent with emission through optically thick thermal bremsstrahlung.

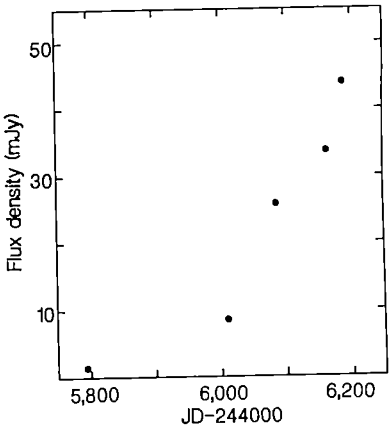

Fig. 1 The radio light curve of CH Cyg at $\lambda = 2$ cm from April 1984 to May 1985.

The radio brightening illustrated by Fig. 1 is reminiscent of symbiotic novae. About six such objects are known, for example, HM Sge, V1016Cyg, RR Tel, and high-resolution maps show shell-like geometries on the sub-arc second scale[5,6]. In contrast, our high-resolution maps of CH Cyg reveal a jet-like feature. Moreover, the 'jet' is clearly expanding at a high velocity. This effect is shown in Fig. 3, where we present maps of CH Cyg at $\lambda = 2$ cm obtained at two epochs with the highest resolution configuration of the VLA. The Smithsonian Astrophysical Observatory catalogue position of CH Cyg, with 1 σ error bars, is shown by the cross on each map. The first map from 8 November 1984 shows two radio components (labelled A and C) with roughly equal flux density separated by 0.18 arc s. On 22 January 1985, 75 days later, the source exhibits an additional component (B), and the separation of A and C appears to have increased to 0.4 arc s. The position of the midpoint between A and C on the two dates agrees to within 0.02 arc s, which is the same to within the accuracy of the measurements and implies that the jet feature is a bipolar phenomenon originating from a point near the position of component B. Extrapolating the rate of expansion backwards in time indicates that components A and C were produced between 22 July and 7 September 1984. This agrees well with the time of onset of radio outburst shown in Fig. 1, and is about 5 months after our first observation in April 1984. This earlier detection might thus be interpreted as a quiescent level of emission or an earlier, weak outburst.

The position, flux density and angular extent of each component in Fig. 2, based on elliptical gaussian fits, are listed in Table 1. From the flux densities and angular sizes, the brightness temperature at 14.9 GHz is about the same for each component and equal to 7×10^3 K, consistent with the equilibrium temperature of a photoionized gas cooled primarily by forbidden line emission. The optical depth of a fully ionized gas at radio wavelengths is given by

$$\tau(\nu)=2.7\times10^{-20}\,\nu^{-2.1}\,T_e^{-1.35}\int_0^w n_e^2\,\mathrm{d}l$$

where ν is the radiation frequency (GHz), T_e and n_e are the electron temperature (K) and density (cm^{-3}), w is, in this case, the width of the jet (cm) and l is the path link. Estimates of the distance to CH Cyg range from less than 200 to 600 pc. Adopting an intermediate value of 400 pc, the typical component width of 0.06 arc s on 22 January, corresponds to $w=3\times10^{15}$ cm. Because the jet is partially optically thick up to 22 GHz, under the assumption of cylindrical symmetry, we can place a lower limit of $2\times10^6\,\mathrm{cm}^{-3}$ on the r.m.s. electron density, yielding masses $M_A > 6\times10^{-7}\,M_\odot$, $M_B > 1.3\times10^{-6}\,M_\odot$ and $M_C > 5\times10^{-7}\,M_\odot$. For distance $D=400$ pc the rate of elongation of the jet corresponds to a projected velocity of 2,100 km s^{-1}. The bipolar expansion velocity is thus $V_e = 1{,}050/\sin i$ km s^{-1}, where i is the inclination of the jet axis to the line-of-sight.

Figure 4 shows the visual light curve of CH Cyg observed by the American Association of Variable Star Observers (AAVSO) from April 1981 to May 1985. Beginning about 1977 the star had been in an optically active state, reaching a peak visual magnitude of about 5.8. This is the highest brightness level observed since monitoring began in 1935. However, the start of the radio outburst coincides with a remarkable decline of 1.5 mag in the visual brightness to the pre-1977 level. This decline of July 1984 was also noted by Tomov[7], who attributed it to a decrease in the blue continuum source based on the fact that the TiO molecular bands of the red giant, which are almost completely filled in by the continuum in earlier spectra, are clearly visible in August and September. He also notes that the Balmer emission had become very wide, expanding to ~2,500 km s^{-1} in Hβ. Selvelli and Hack[8] also observed a large increase in the Balmer line widths between July and November 1984. They report a full width of 3,950 km s^{-1} for Lyα in November 1984 and January 1985.

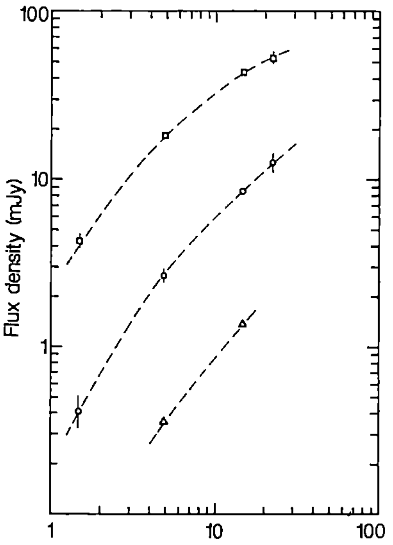

Fig. 2 Radio continuum spectra of CH Cyg at three epochs: □, 3 May 1985; ○, 8 November 1984; △, 6 April 1984.

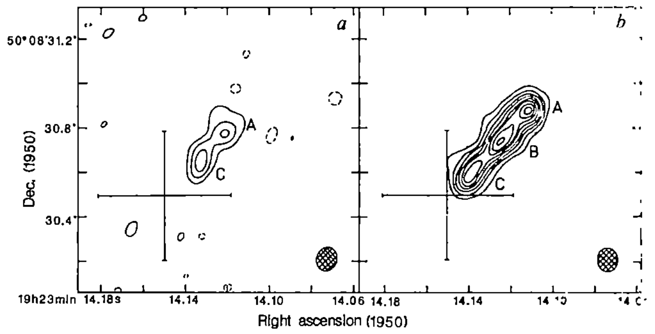

Fig. 3 VLA radio maps at $\lambda=2$ cm separated by 75 days (*a*, 8 November 1984; *b*, 22 January 1985) showing the evolution of the jet. The half-power ellipse of the synthesized beam is indicated at lower right.

We have considered two possible explanations for the expanding jet feature: (1) the propagation of an ionization front from a highly directional source of ionizing photons; and (2) the outward motion of ionized material along an axis defined by the central power source. The sudden turn on of a hot source that emits L_{ph} ionizing photons per second will produce an ionization front propagating outward at a velocity roughly given by $v=L_{ph}/4\pi r^2 n_H$, where n_H is the constant number density of hydrogen atoms. Taking $n_H=2\times10^6\,\mathrm{cm}^{-3}$ and L_{ph} sufficient to ionize material to an angular distance of 0.2 arc s yields $v\simeq$ 2,000 km s^{-1} for $D=400$ pc. A model of this type can thus account for the observed expansion rate. It seems, however, unlikely that a rapidly propagating front should be produced at a time when the optical luminosity is decreasing; although it is possible that most of the flux has shifted to the ultraviolet, as is observed during the optical decay of novae. Another difficulty is that, in the case of a propagating front, one expects the structure of material behind the ionization front to remain roughly constant. Such a model is therefore difficult to reconcile, in a straightforward manner, with the appearance, at a later date, of a third component interior to the front. If the material of component B were present on 8 November, it should have been visible.

The radio data thus favour a material flow model. Such an interpretation is further strongly supported by the appearance of high-velocity Balmer emission at the time of the onset of the optical decline and radio outburst. If the radio jet represents outflowing material, a lower limit on the rate of mass ejection is provided by the fact that component B is absent on 8 November. The mass M_B must have been ejected over an interval of <75 days, yielding a mass ejection rate $\dot{M}_e > 7\times10^{-6}\,M_\odot\,\mathrm{yr}^{-1}$ for $V_e > 1{,}050$ km s^{-1}. The energy flow involved in the mass loss

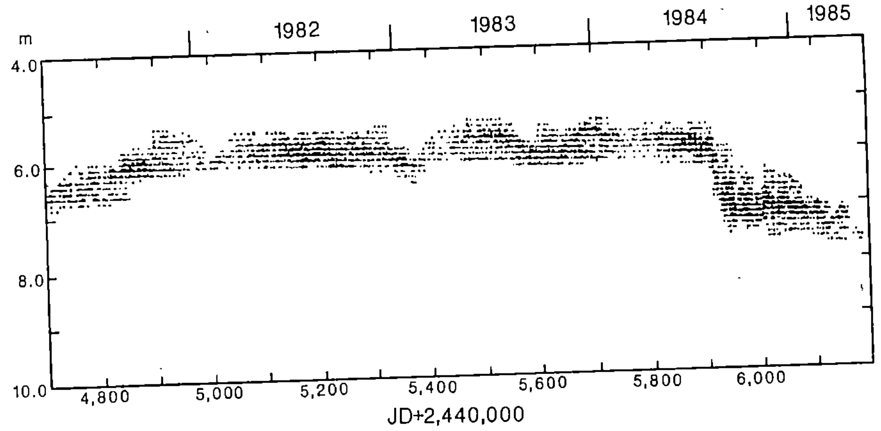

Fig. 4 The AAVSO visual light curve of CH Cyg from April 1981 to May 1985. Each dot represents one observation.

is $>3\times10^{36}$ erg s^{-1}, and the total kinetic energy of the bulk motion is $\geqslant10^{43}$ erg. The energetics of the mass flow is thus similar to that observed in nova shells, and points to an origin in an event having total luminosity of the order of at least 10^{37} erg s^{-1}. Luud *et al.*[9] pointed out that the integrated ultraviolet flux measured in September 1981 yields a luminosity of $\sim10^{38}$ erg s^{-1}. The total radiative luminosity at maximum light is thus sufficient to power the outflow.

It has been suggested previously that the CH Cyg system contains an accretion disk[10,11]. Most notably, Slovak and Africano[10] have observed optical continuum flickering on a timescale of a few minutes. Such flickering is common among cataclysmic variables, where it is attributed to a hotspot on an accretion disk around a white dwarf. In the case of CH Cyg, the timescale of the flickering implies an upper limit of $\sim10^{10}$ cm in the radius of the accreting object. We are therefore led to the suggestion that the energy required for the creation of the jet feature is produced by accretion onto the surface of a compact object. For a $1 M_\odot$ object with radius R the critical rate at which the accretion-generated luminosity exceeds the Eddington limit is given by

$$\dot{M}_{\rm cr}\simeq10^{-3}\left(\frac{R}{R_\odot}\right)\qquad M_\odot\,{\rm yr}^{-1}$$

For $R<10^{10}$ cm, $\dot{M}_{\rm cr}\leqslant10^{-4}\,M_\odot\,{\rm yr}^{-1}$, and for a white dwarf $\dot{M}_{\rm cr}\simeq10^{-5}\,M_\odot\,{\rm yr}^{-1}$. These accretion rates are comparable to the mass loss rate in the jet. Since during an accretion driven outburst $\dot{M}_{\rm e}$ will be less than or, at most, equal to the rate of accretion, $\dot{M}_{\rm acc}$, onto the central object, we infer that for the event leading to the CH Cyg jet $\dot{M}_{\rm acc}\geqslant\dot{M}_{\rm cr}$. From the calculations of Shakura and Sunyaev[12], accretion through a disk at a rate close to, or exceeding, the Eddington limit can produce a radiation-driven outflow of matter along the angular momentum axis of the disk. Bath[13] has modelled such an outflow and finds that outflow velocities of a few thousand km s^{-1} can be obtained from supercritical accretion onto a white dwarf, and expected mass ejection rates are $<0.5\,\dot{M}_{\rm cr}$, in excellent agreement with the observations. The ultraviolet luminosity before the radio outburst suggests that the accretion rate has been near, or at, supercritical since 1981.

The formation of a massive disk and accretion rates of the order $10^{-5}\,M_\odot\,{\rm yr}^{-1}$ imply that mass transfer occurs through Roche lobe overflow from the red giant. Accretion rates from the red giant wind alone will be much too small, typically $10^{-8}\,M_\odot\,{\rm yr}^{-1}$ or less. A number of periods, both spectroscopic and photometric, have been reported for CH Cyg, ranging from about a month to many years. The fact that since 1977 CH Cyg seems to spend most of the time in an optically active state, that the luminosity has been near supercritical since at least 1981 and that flickering has been observed at many epochs, indicates that a high accretion rate persists for a large fraction of the orbital period. For a radius of the M7III primary of $R_*=200\,R_\odot$ (ref. 14), a maximum orbital separation of about $2R_*$ (for high mass transfer rate through the inner lagrangian point) would require an orbital period of $\leqslant3$ yr.

An object with radius typical of a white dwarf and luminosity $L\sim10^{38}$ erg s^{-1} will have a surface temperature $T=10^5$–10^6 K, and might be detectable as an X-ray source. In this regard, it is noteworthy that CH Cyg lies near the centre of the error box of the HEAO A-2 hard X-ray source H1926+503 (ref. 15). If the X-ray flux is associated with CH Cyg, the luminosity, measured in November 1977 when the source was entering the optically active state, is $\sim10^{33}$ erg s^{-1}, consistent with optically thick accretion through a disk onto a white dwarf at a rate $\geqslant10^{-7}\,M_\odot\,{\rm yr}^{-1}$ (ref. 16). X-ray observations of CH Cyg during the outburst will be very important.

The radio outburst from CH Cyg is an unusual and complex event, and, while we have presented a preliminary picture to account for the phenomenon, some problems remain. Although the observational evidence strongly supports a material flow model, a propagating ionization front cannot be ruled out. In either case, it is difficult to reconcile the optical decline with either the radiation required for the ionization or the energy for the mass flow. Further observations are clearly needed. A measurement of the ultraviolet luminosity will be particularly valuable. The spectral evolution during the decay of the radi outbursts will also provide important clues. The radio deca should be accompanied by a flattening of the radio spectra index as the material expands and becomes optically thin.

The only other symbiotic star known to exhibit a jet-lik feature is R Aqr[17]. This feature, which appeared some tim between 1970 and 1977, was first detected optically as a emission spike[18,19]. An ejection model for this source[20] has bee questioned because no proper motion of the components ha been observed[21]. Spergel *et al.*[22] have suggested instead that th appearance of the 'R Aqr jet' was the result of sudden photoio ization of condensations in the red giant wind. More recentl Solf and Ulrich[23] have successfully modelled the kinematics the nebulosity about R Aqr in terms of two episodes of bipol shell ejection 185 and 640 yr ago, with total shell mass $\sim10^{-5}\,M_\odot$ and expansion velocity of the order of 100 km s^{-} The CH Cyg outburst provides the first opportunity to obser an event giving rise to a radio jet from a symbiotic star. It w be important to follow the evolution of the CH Cyg jet at rad and other wavelengths, both to clarify the nature of the outbu and jet formation and to study the kinematics of the jet co ponents at large radii.

Mechanism of stable jet formation in electrohydrodynamic atomization

The disruption of a liquid into a spray of charged droplets, when subjected to an intense electric field, has attracted considerable interest from both a fundamental and applied point of view. On the applied side, the process has been used in paint spraying, electrostatic printing, electrostatic emulsification, fuel atomization in combustion systems and in space vehicle propulsion systems. More recently, the phenomenon has found potential application in crop spraying because of the low energies required, the ability to produce fine sprays within a narrow size distribution and the preferential deposition on the target surfaces. Despite its wide range of applications, the mechanism of liquid disruption is only poorly understood. At a critical potential, the so-called Taylor[1] cone develops, with a fine stable jet issuing from its tip. The formation of such cones and jets is essential for the production of an electrohydrodynamic spray. Most previous work aimed at understanding jet formation has been based on high-speed photographic techniques. We have made direct observations of jet formation and our results, presented here, demonstrate the role of electrical shear effects in this process, and invalidate those theories that assume a uniform velocity profile[2] for the liquid in the conical base of the jet.

If a large potential (up to ~15 kV) is gradually applied to a capillary through which a semiconducting liquid is flowing slowly, the size of the emergent drop decreases while the dripping rate increases. At a certain potential the drop at the end of the capillary ejects a small drop or a long filament. This filament breaks off and the meniscus of the drop relaxes back to its initial shape in a pulsating fashion, the rate of which increases with an increase of potential. At a critical potential, depending on the conductivity of the liquid, the main drop develops into a cone—the Taylor[1] cone—with a fine stable jet issuing from its tip; this is a prerequisite for the production of an electrohydrodynamic spray, which consists of a symmetrical assembly of such jets around the capillary or nozzle. Despite the importance of stable jets, their mechanism of formation remains unclear. It is known, for example, that not all liquids form such stable jets and that effective atomization can only be achieved if the conductivity of the liquid is within the limits 10^{-6}-$10^{-8}\ \Omega^{-1}\ \mathrm{m}^{-1}$ (that is, a semiconducting liquid). In previous work aimed at understanding jet formation, theoretical treatments assumed a uniform velocity profile within the Taylor cone and certain authors[1,3] regarded the cone as an equipotential surface. Here we decided to study the movement of the liquid as it emerges from the capillary and forms the Taylor cone.

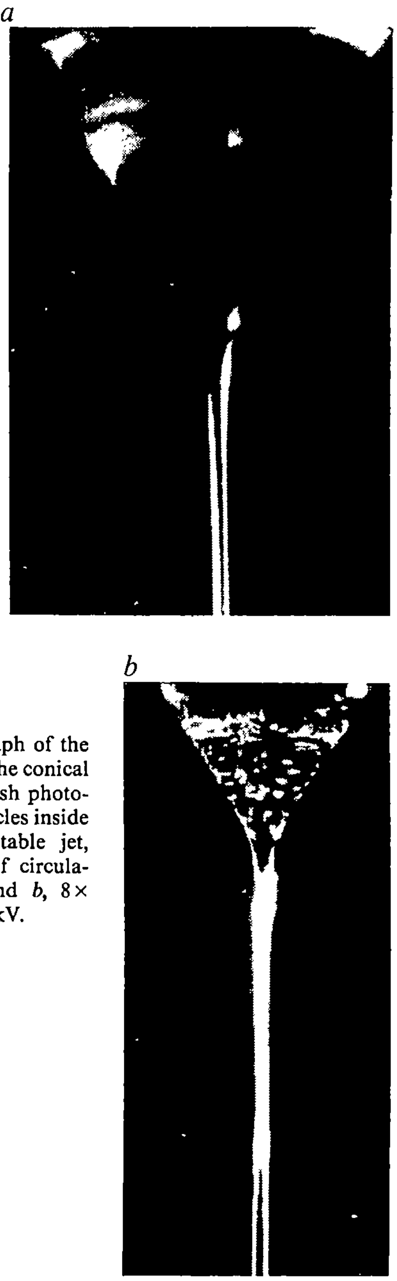

Fig. 1 *a*, Streak photograph of the circulation pattern within the conical base of a stable jet. *b*, Flash photograph of lycopodium particles inside the conical base of a stable jet, indicating the direction of circulation. Flow rate for *a* and *b*, $8\times10^{-9}\ \mathrm{m}^3\ \mathrm{s}^{-1}$ at 10.5 kV.

To observe the movement of the liquid at the base of the jet, we chose a relatively large capillary, of 1-2 mm diameter, so that the dimensions of the cone were not too small, and tracer particles, lycopodium powder, were added to the liquid. The region of interest was observed and simultaneously photographed at a magnification of about ×30 using a microscope. The experimental set-up consisted of a metal capillary, to which

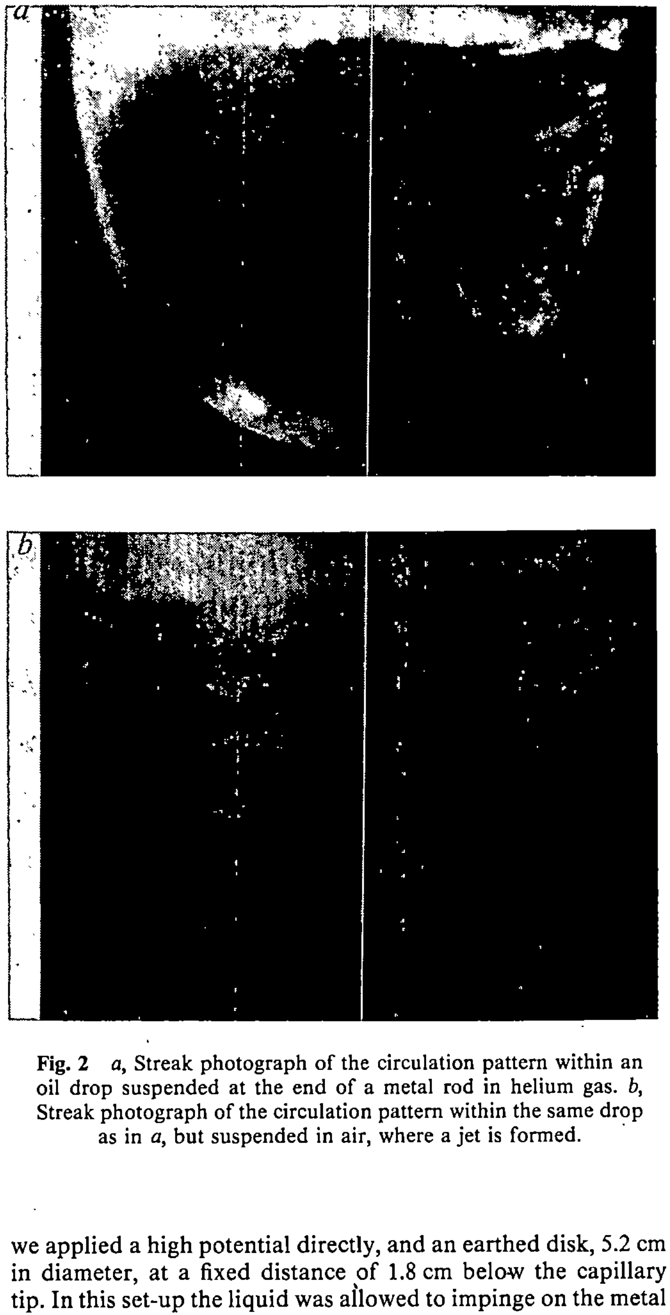

Fig. 2 *a*, Streak photograph of the circulation pattern within an oil drop suspended at the end of a metal rod in helium gas. *b*, Streak photograph of the circulation pattern within the same drop as in *a*, but suspended in air, where a jet is formed.

we applied a high potential directly, and an earthed disk, 5.2 cm in diameter, at a fixed distance of 1.8 cm below the capillary tip. In this set-up the liquid was allowed to impinge on the metal disk. The liquid used was an isoparaffin oil, Isopar M, to which we added *n*-butanol to bring the conductivity within the required limits (see above). The rate of flow of the liquid (8×10^{-11} to 88×10^{-8} m^3 s^{-1}) was controlled using a perfusor pump. The jets were illuminated with white light and photographed using a camera.

As the potential was applied and a stable jet was formed, we observed a very clear axisymmetric circulation of the particles in the conical base of the jet. Good streak photographs of this motion were difficult to obtain, but Fig. 1*a* shows this circulation pattern, produced at a flow rate of 8×10^{-9} m^3 s^{-1} (10.5 kV). The direction of motion, which could be identified easily by looking through the microscope, is of great interest. The particles were seen to come down the surface of the cone and reverse upwards along its axis; this was confirmed by taking photographs using a flash light. The light generated by the flash fades after it is triggered so that a moving particle will develop a faint streak in the direction of its motion. Such a photograph is shown in Fig. 1*b*; particles near the axis of the cone have a faint streak pointing upwards. This result is of great significance because it indicates that there is a backflow at the centre whereas the velocity is greatest at the surface of the liquid. This represents almost the opposite of the velocity distribution for laminar flow in a tube, where the velocity is zero at the wall of the tube and maximum at the centre. This direct observation of circulatory flow invalidates those theories which assume a uniform velocity profile[2] for the liquid in the Taylor cone.

The origin of this circulation may be understood by reference to a review by Melcher and Taylor[4] on electrohydrodynamic shear stresses; they pointed out that for an interface to be subjected to a shear stress, the surface must simultaneously support surface charge and be subjected to a tangential electric field. These two conditions are both satisfied in the present system. The electric field within the liquid will drive free charges to the surface of the cone, hence the surface is charged and is subjected to a normal electric field, E_n. Because of the semiconducting nature of the liquid, a potential difference will exist between the base of the cone at the end of the capillary and the tip of the cone. This potential difference ensures that the interface is subjected to a tangential electric field, E_t, in the direction of flow, and hence an electric shear stress on the surface of the cone

$$\tau_t = \varepsilon_0 E_n E_t$$

where ε_0 is the permittivity of free space. This shear stress causes the axisymmetric convection currents within the Taylor cone that are reported here for the first time.

The velocity profile within the cone was analysed by solving analytically the equations of motion for creeping flow in axisymmetric spherical coordinates. The solution of these equations will be given elsewhere[5]. It is sufficient to mention here that the calculated velocity profiles are consistent with those shown in Fig. 1. Such convection currents were not detected within a water cone, because the high conductivity of water ensures that the cone is almost an equipotential surface. Although the surface is charged it is not subjected to a tangential electric field and shear stress.

Another demonstration of the circulatory motion due to electrohydrodynamic shear stresses was provided by observations of pendant drops inside a glass chamber which could be filled with various gases. We observed that the distortion of a drop hanging from a metal rod connected to a high potential depends on the breakdown potential of the gas. If the breakdown potential is lower than that required to cause instability of the liquid, the atmosphere becomes conducting and no stable jet can be formed. Examples of such gases are He and Ne. For these gases, glow discharges were observed in the dark, and with a semiconducting liquid the flow extended from the edges of the rod down to the earthed plate. The drop was enveloped by the electric discharge. The addition of lycopodium powder to the liquid revealed an axisymmetric circulatory motion but in the opposite direction to that observed within the cone of Fig. 1—that is, near the surface the particles moved upwards and near the centre line of the drop they moved downwards. Figure 2*a* shows the circulation within an oil drop surrounded by He gas.

Again this circulation can be explained as being due to electrical shear effects. The surface of the drop supports free charge due to the field applied, which drives the charges from the bulk to the surface. Hence the first condition for shear stresses to occur is satisfied. The discharge at the edge of the rod where it is in contact with the liquid creates a local potential drop near that region. Hence, the potential at the tip of the drop will be higher than at its edges. This potential difference produces a tangential field and hence a tangential stress across the surface of the drop in the upward direction, and creates the convection currents observed within the drop. If the voltage is increased slightly, a stronger discharge is produced and the motion becomes faster, sometimes causing the drop to climb up the metal rod. If the helium input is stopped and air gradually fills the glass chamber, the discharge disappears and the circulation stops. On further increase in the voltage, the drop develops into a Taylor cone and from its tip a thin jet is ejected. As soon as this occurs, a circulation pattern is observed (Fig. 2*b*), the direction of the circulation being the same as that in Fig. 1.

When a pendant drop of a conducting liquid such as water was surrounded by helium, the discharge originated at the surface of the drop itself rather than at the rod, and extended to the earth plate. When tracer particles were introduced into this water drop, no motion of the particles could be observed. Instead, all the particles settled at the bottom of the drop. Again, this result is attributed to the high conductivity of water, which forms an equipotential surface; hence the surface is not subjected to a tangential field.

The above observations clearly demonstrate the role of electrical shear effects in the process of formation of a stable jet. These shear stresses resulting from the electric field within the cone and further down the jet produce a downward longitudinal force which stabilizes the jet by smoothing any perturbations on the surface. As one moves downwards from the cone, the electric field within the jet gradually decreases and so does the shear stress. A point is reached at which the radial force exceeds the shear force, thus causing disruption of the jet into a brush of thin jets which ultimately break into a monodisperse spray; this was confirmed by careful observations of the jet at the point of break-up for semiconducting liquids. With conducting liquids such as water, there is no build-up of electric field within the jet and hence there will be no tangential stress; the jet suffers only the destabilizing effect of the radial stresses and an unstable spray is produced.

The direction of the circular motion within the liquid cone, as demonstrated here, indicates that the jet is formed by the stripping of the drop surface rather than by the pulling of the liquid from the bulk of the drop or the detachment of small droplets from the liquid apex[6]. Thus, it seems that the movement of the thin surface layer of liquid relative to the bulk of the cone under the effect of surface-charge gradients is analogous to the Gibbs–Marangoni effect[7,8] where the movement of a thin liquid film occurs under the effect of surface-pressure gradients.

We thank Mr D. Maw for taking the flash photograph.

Fractal characterization of inhomogeneous geophysical measuring networks

S. Lovejoy*, D. Schertzer* & P. Ladoy†

* Physics Department, McGill University, 3600 University Street, Montreal, Quebec, Canada H3A 2TB
† EERM/CLIM, Météorologie Nationale, 2 Ave Rapp, Paris, 75007, France

The measuring stations of most *in situ* geophysical networks are spatially distributed in a highly inhomogeneous manner, being mainly concentrated on continents and population centres. When inhomogeneity occurs over a wide range of scales in a space of dimension E, it can be characterized by a fractal dimension D_m. For measuring networks, there is no reason to assume *a priori* that D_m equals E; it will usually be less than E. The world meteorological network studied here is an example on a surface for which $E=2$ (the surface of the Earth) whereas, the network has an empirical dimension $D_m \simeq 1.75$. Whenever $D_m < E$, any sufficiently sparsely distributed phenomena (with dimension $D_p < E - D_m$, here 0.25), cannot be detected—even if the network is infinite. Because these rare phenomena are the most intense, this insufficient dimensional resolution is associated with biases in geophysical statistics, serious difficulties in interpolating measurements to a uniform grid, and problems in calibrating remotely-sensed information.

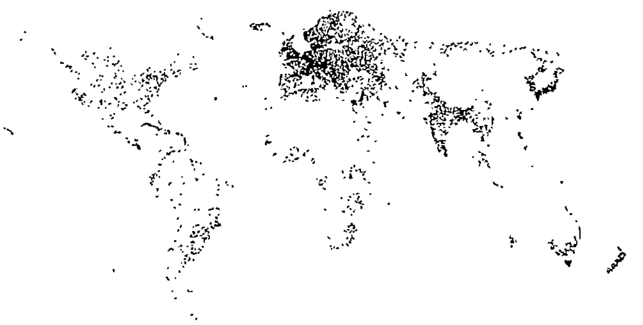

Fig. 1 The locations of the 9,563 stations in the global meteorological measuring network (defined as the stations which the World Meteorological Organisation lists as performing at least one meterological measurement per day), showing their high degree of non-uniformity. Most are clustered on the continents and major industrial areas. The dimension (D_m) is ~1.75.

The intuitive notion of dimension D_m of a set (whether fractal or otherwise) is given by the variation of the number of points ($\langle n(L)\rangle$) with the size of the region (L):

$$\langle n(L)\rangle \propto L^{D_m}$$

When D_m is less than the dimension (E) of the space in which the set is embedded, when L increases, the volume of space available increases as L^E which is faster than the number of points of the set that are available to fill it ($\langle n(L)\rangle$). Hence, larger and larger 'holes' (empty regions) appear and the set is concentrated on a decreasing fraction of the total space. Furthermore, at a given scale, sets with lower D_m are more dominated by holes, and are hence more sparse.

Although there are many ways of estimating the dimension of sets of points, many of which have been developed for studying strange attractors[2–5] they generally yield similar results. The method used here, actually determines a particular dimension called the correlation dimension[6]. To apply this method to a geophysical network (considered here as a set of points), determine, for each station in the network, the number ($n(L)$) of other stations within various radii L of the point, and its average $\langle n(L)\rangle$ over all the stations. We then obtain D_m as the slope of $\log\langle n(L)\rangle$ against $\log L$. Scales over which $\langle n(L)\rangle$ varies non-algebraically, define the characteristic lengths of the network.

To apply this technique to a surface network (such as the highly clustered world meteorological network, Fig. 1), we must discuss a complication that takes into account the curvature of the Earth's surface. If the latter is covered uniformly with stations in a region of area S, then $\langle n(L)\rangle \propto S$. Taking $S(\theta)$ as the area of the spherical cap defined by two points subtending an angle θ at the Earth's centre (radius r) we may define the corresponding scale $L(\theta)$ by:

$$S(\theta) = (\pi/4)L^2(\theta) = 2\pi r^2(1-\cos\theta/2)$$

Note that with this definition of L, for small θ, the formula reduces to the usual great circle distance ($= r\theta$), and we recover $D_m = 2$ when the stations are homogeneously distributed.

Figure 2 shows $\langle n(L)\rangle$ calculated using the above L, for the 9,563 stations in this network separated by at least 0.01° of arc

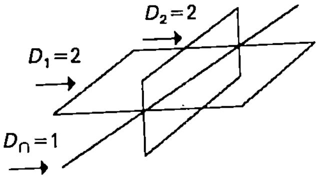
(~1 km, the accuracy of the data). Avoiding double counting, each station defines 9,562/2 = 4,781 values of L, hence there are 9,563 × 4,781 = 45,720,703 independent values that go into the histogram for estimating $\langle n(L)\rangle$. Figure 2 shows that roughly between the minimum resolvable scale, (~1 km) and ~2,000 km, $\langle n(L)\rangle \propto L^{1.75}$, hence $D_m \sim 1.75$. The size of the scaling regime is limited as the number of points is finite: $\langle n(L)\rangle_{\max} = 4{,}781$ and $\langle n(L)\rangle_{\min} \sim 1/9{,}563 \sim 10^{-4}$. Assuming $L^{1.75}$ between these limits implies $L_{\max} \sim 7{,}500$ km, $L_{\min} \sim 0.3$ km, which shows that the scaling observed in Fig. 2 spans a range nearly as large as is possible. Similar analysis of the French climatological network (3,593) stations yielded $D_m \sim 1.8$, while the Canadian meteorological network (414 stations) yielded $D_m \sim 1.5$.

The fact that $D_m < E$, sets new detectability limits. A network, dimension D_m can detect a phenomenon with dimension D_p, only if the two sets intersect. However, a theorem in geometry shows that this is certain to occur only when $D_p > E - D_m$. Two sets, dimension = D_1, D_2 embedded in a space dimension = E, intersect on a set dimension = $D_\cap$. (With the co-dimension $C = E - D$) according to the following rule:

$$C_\cap = \mathrm{Inf}((C_1 + C_2), E)$$

Example. Intersection in space ($E = 3$) of two planes

$$(D_1 = D_2 = 2 \Rightarrow C_1 = C_2 = 1)$$



$$C_\cap = C_1 + C_2 = 2 \Rightarrow D_\cap = E - C_I = 1$$

Although the example is for two standard sets (planes) it holds for most fractal sets. Note that if $C_m + C_p > E$, the intersection set probably has dimension zero ($C_\cap = E$), hence, the sets typically miss each other. Hence, in the case studied here, sparse surface phenomena with $D_p < 2 - 1.75 = 0.25$, cannot be detected. In analogy with the network's spatial resolution, which is the minimum detectable scale, we may define, its dimensional resolution as $E - D_m$ which is the minimum resolvable dimension.

The inability to detect sparse phenomena is serious because, in general, we expect geophysical fields to be characterized by multiple fractal dimensions[6-9]. In turbulence, fields are generally characterized by multiple fractal dimensions[10-13]. In geophysics, there is empirical evidence for multidimensionality in the rainfield[14,15]. If a field is multidimensional, then regions exceeding a threshold T define fractal sets with dimension $D_p(T)$ decreasing with T. Thus, whenever averages are taken over sets with $D_m < E$, then, by the intersection theorem, the most intense fractals (with $D_p(T) < E - D_m$) are missed. While both mono- and multidimensional fields have statistical properties that are functions of scale, multidimensional fields are in addition dependent on the dimension (for example, line, plane, volume or fractal set) over which they are averaged.

We have argued that the characterization of network inhomogeneity by the fractal dimension (D_m) raises new problems concerning the detectability of sparse phenomena. Since phenomena (of any size) with $D_p < E - D_m$ will not intersect the network, we have obtained a new criterion for evaluating measuring networks: to detect phenomena, not only must a network have sufficient spatial resolution it must also have sufficient dimensional resolution. In general, we expect the fractal dimension of geophysical fields to be a decreasing function of intensity: thus, any lack of dimensional resolution leads to biases in the spatial averages. Finally, as information on the lowest dimensional fractals is lost, similar biases will arise when measurements are interpolated to uniform grids with dimension E.

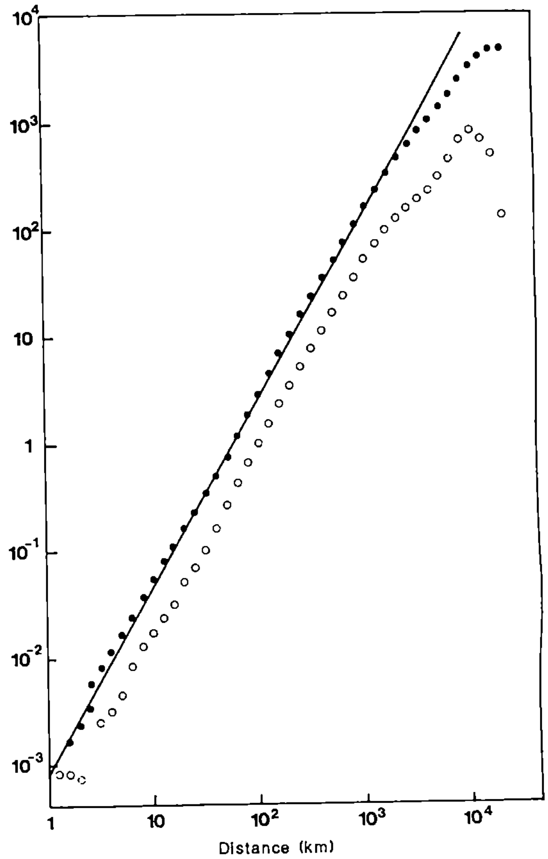


Fig. 2 ○, The average number of stations within annuli of geometrically increasing radii; ● (the integral of the previous function), the function $\langle n(L)\rangle$ described in the text. Over the scaling regime, both should be parallel and straight: the $L^{1.75}$ function is shown for reference. The scaling regime apparently continues down to scales comparable with the accuracy of the geographical locations used to determine L(~1 km) which is, therefore, the spatial resolution of the network. For comparison, the standard analysis method (which assumes $D_m = 2$, a surface area of ~10^8 km^2, and 10^4 stations), attributes an average area of $10^8/10^4 = 10^4$ km^2 per station hence a spatial resolution of ~10^2 km^2 which is about 100 times larger than its true resolution.

The absence of redbeds, the occurrence of readily oxidizable minerals in placers, and the rarity of sulphate minerals are some features which suggest generally reduced conditions on the Earth's surface during Archaean time[1]. Supporting this conjecture are $\delta^{34}S$ values near 0‰ for sulphides of sedimentary rocks[2–4] and massive sulphide deposits[5], since isotopic fractionation requires oxidation–reduction reactions. The flux of oxidized species during the Archaean produced by fixation of organic carbon was, however, comparable with modern levels[6], but was largely consumed by reactions with a large supply of reduced mantle material[4,7]. Notable occurrences of Archaean sulphate are ~3,400-Myr stratiform barites in Australia[8,9], South Africa[10] and India[11], with $\delta^{34}S$ ~+4‰ (refs 8–10) which are believed to have formed by bacterial oxidation of primary (0‰) sulphide[10]. Consideration of the Archaean sulphur cycle has focused on sulphate of this origin. We draw attention here to sulphate of different isotopic composition, +8 to +14‰, of magmatic origin, that contributed to the total flux of oxidized species during the Archaean.

Occurrences of sulphate minerals in Archaean terrane (Table 1) have been divided into vein and stratiform types. These are mainly barite or anhydrite. Where gypsum is found, it appears to have formed by hydration of primary anhydrite at low temperatures. It is important to establish first that these sulphates are of Archaean age and were not introduced by later processes. We have used Sr isotope determinations for this purpose. As both barite and anhydrite generally contain >1,000 p.p.m. (parts per 10^6) Sr and negligible Rb, measured and initial $^{87}Sr/^{86}Sr$ ratios are the same. Most samples are of late Archaean age (2,800–2,600 Myr) and have ratios in the range 0.7013–0.7021 (Table 1). This is comparable with initial ratios of magmatic rocks of this age, for example, 0.7014 to 0.7018 for mafic volcanic rocks from the Abitibi belt, Canada[12] and 0.7013 for mafic volcanic rocks from Kambalda, Australia[13]. Values for felsic intrusives are in a similar range[14,15] except for higher ratios for intrusives derived by partial melting of pre-existing rock[16].

The low $^{87}Sr/^{86}Sr$ ratios of sulphate minerals are taken to indicate that these sulphate minerals formed during volcanism or during the following plutonism and metamorphism of the belts. Because of the secular increase in the Sr isotopic composition of ocean water[17] and igneous rocks[14], their formation at a later time, that is, in the Proterozoic, from either of these sources, would produce higher $^{87}Sr/^{86}Sr$ ratios. Furthermore, solutions passing through Archaean rocks at a later time may gain ^{87}Sr produced by decay of ^{87}Rb. Based on their Sr isotope values, we have eliminated some occurrences within Archaean rocks, for example, barite veins in volcanic rocks in the Thunder Bay district with values >0.710 (ref. 18) and barite veins in the Timmins–Matachewan area with ratios of 0.7030 to 0.7050 (ref. 18). In both cases, some of the veins of similar occurrences in the areas cut Proterozoic rocks, confirming their post-Archaean origin.

Most of the vein occurrences referenced in Table 1 are associated with gold mineralization. The time relationship of the sulphate veins with gold mineralization varies from pre-gold and penecontemporaneous with the host intrusive (McIntyre Mine[19]); contemporaneous with the gold mineralization (Golden Mile, Kalgoorlie (J. M. F. Clout and E.M.C., unpublished data), Lac Shortt[20]); to post-gold (Lake Shore and Macassa Mines[21]). At Lake Shore and Macassa in Kirkland Lake the sulphates occur in shear zones. Since mineralization and igneous activity took place during the Archaean, the associated sulphate also probably formed at this time. The continuous movement of the shear zones during the late Archaean and Proterozoic may explain their high $^{87}Sr/^{86}Sr$ ratios (Table 1), by incorporation of radiogenic Sr.

Reported occurrences of stratiform barite have been from older (≥3,000 Myr) Archaean rocks. Until recently there was no known occurrence in Archaean strata of North America, which are mostly 3,000–2,670 Myr (ref. 22). Elsewhere, the only barites that may be stratiform and late Archaean are in the Bulawayan Group of Zimbabwe, but their genesis and age are uncertain[23]. In 1981, the large Hemlo gold deposit, near Marathon, Ontario, was discovered. The tabular ore bodies appear to be stratiform near the facies contact between volcaniclastic and epiclastic sedimentary rocks. The main ore zone and footwall rocks contain massive barite layers and lenses up to 10 m in thickness[24]. More recently, massive barite bands, which are discontinuous but on strike >6 km within a metasedimentary sequence, have been found 21–26 km west from the Hemlo mineralization[25].

Whereas $\delta^{34}S$ values for the Barberton and North Pole barites are ~+4‰, most of the other sulphate minerals are in a range of +7 to +14‰. This is too large to be explained by simple oxidation of primary magmatic sulphide. Sulphates of this composition could only have formed by two processes: ^{34}S-enrichment of biologically-produced sulphate of ~4‰ by its partial reduction to ^{34}S-depleted sulphide; or formation by magmatic or magmatic–hydrothermal processes with $\delta^{34}S$ values being determined by inorganic isotopic exchange reactions at high temperature.

Sulphate in igneous rocks is formed by two processes: oxidation of primary sulphide in silicate magma (magmatic sulphate) and hydrolysis of SO_2 gas in aqueous fluids (magmatic–hydrothermal sulphate). The solubility of sulphur in silicate melts depends on oxygen fugacity (f_{O_2}) as well as temperature and pressure[26], and the contents usually range from ~800 to ~1,100 p.p.m. in mafic volcanic rocks[27–29]. Felsic magmas may have contained more[30], although they tend to lose most of the sulphur during intrusion and solidification. Most of this sulphur is present as sulphide and sulphate with the relative proportions controlled by f_{O_2} (ref. 26). The f_{O_2} is determined by the mineral assemblages[26,28], principally the Fe^{3+}/Fe^{2+} ratios, as the amount of iron is far larger than that of sulphur. Overall reaction for the oxidation of sulphur in silicate magma is expressed as[28]

$$S^{2-}(\text{melt}) + 4H_2O = SO_4^{2-}(\text{melt}) + H_2 \tag{1}$$

Evidence for this process is a correlation between the water and sulphate contents in basaltic glass[28] and an increase in δD values of water in pillowed basalt due to degassing of low δD gas, such as CH_4 and/or H_2 (ref. 31). Selective degassing of H_2 from magma causes reaction (1) to move to the right, oxidizing the magma[28]. Such magmatic sulphate comprises 15–36% of the total sulphur[28,29]. The magmatic sulphate is retained in the glass phase on solidification.

In a more open system, such as subaerial extrusives, much of the sulphur is lost as gas, SO_2 (refs 29, 32), reducing the magmatic sulphate content in the remaining silicate melt, often to <30 p.p.m., and f_{O_2}. The escaping SO_2 gas from magma is eventually hydrated to SO_4 in the atmosphere by the following reactions, even in low p_{O_2} (partial pressure of O_2) conditions:

$$SO_2 + H_2O + 1/2\,O_2 = H_2SO_4 \tag{2}$$

SO_2 gas dissolved in an aqueous fluid in igneous rocks at high temperatures will hydrolyse to form sulphate in the magmatic-hydrothermal system[33]:

$$SO_2(\text{gas}) + 2H_2O = H_2SO_4 + H_2(\text{gas}) \tag{3}$$

Diffusive loss of H_2 gas will move the reaction to the right. At temperatures below the H_2O-saturated solidus, hydrolysis of SO_2 can also yield H_2S gas and sulphate[33]:

$$4SO_2(\text{gas}) + 4H_2O = H_2S(\text{gas}) + 3H_2SO_4 \qquad (4)$$

Precipitation of the sulphate by reaction with Ca^{2+} to form anhydrite in aqueous fluid moves the reaction to right.

Epizonal intrusives are particularly suitable for developing sulphate of this latter origin. The low lithostatic pressure facilitates the exsolution of H_2O and S from silicate magmas; brecciation due to the secondary boiling, which allows escape of gas phases; and ready access to surface water. The occurrence of sulphate minerals in the hydrothermal system of porphyry copper mineralization is well documented[34,35].

The sulphur isotopic composition of magmatic sulphate will depend on the temperature, the ratio S^{2-}/SO_4^{2-}, and the primary S isotopic compositions of the magma, which is ~0‰ for Archaean magmas because of lack of contamination of sedimentary rocks containing sulphide of $\delta^{34}S$ different from 0‰. The isotopic fractionation factor, α, in melts[36] at 600–1,000 °C is:

$$1{,}000 \ln(\alpha_{SO_4^{2-}-S^{2-}}) = 7.4 \times 10^6/T^2 - 0.19$$

where T is in K. $\alpha_{SO_4^{2-}-S^{2-}}$ is 5‰ at 900 °C, 8‰ at 700 °C and 9‰ at 600 °C. There may be re-equilibration in silicate glass during cooling after solidification, giving lower apparent formation temperatures[28]. Because sulphide is dominant in most magmas, it will show the least departure from the primary isotopic composition of 0‰, with sulphate being in the range of +7 to +12‰ (refs 28, 29). However, degassing of H_2 can increase the sulphate content, causing $\delta^{34}S$ for the latter to decline, for example, Hawaiian subaerial flows[29]. $\delta^{34}S$ for sulphate in magmatic-hydrothermal fluids are larger than that of magmatic sulphate because of lower temperatures of the fluids compared with melts.

When $\delta^{34}S$ for total S is ~0‰, $\delta^{34}S$ values of magmatic sulphate will mostly be in a range of +7 to +10‰ for mafic rocks formed at ~1,000 °C and higher, to ~+12‰ in felsic rocks with lower solidification temperatures. The values of magmatic-hydrothermal sulphate formed in aqueous fluids is mostly in the range of +8 to +14‰ (refs 35, 37). An important point is that the rate of formation of magmatic and magmatic-hydrothermal sulphate is independent of the atmospheric oxygen pressure. It is dependent on the intensity of volcanism over a given time and the tectonic conditions in which this takes place.

For the vein sulphates listed in Table 1, which are mostly associated with intrusions and which have δ^{34}S values of +8 to +13‰, it is reasonable to suggest that these are of magmatic-hydrothermal origin. They are analogous to the veins of anhydrite on Phanerozoic porphyry mineralization. What is less certain is the origin of the +8 to +13‰, tabular sulphate body parallel to bedding, such as that at the Hemlo main deposit and barite occurrences west of Hemlo. These appear to have precipitated by the interaction of Ba^{2+}-rich fluid and sulphate-rich water[24]. This requires the earlier accumulation of sulphate in the surface water since sulphate was generally poor in the Archaean, both in continental and submarine environments.

There are two possible origins for this sulphate: (1) biological oxidation of primary sulphide to form ~0 to ~+5‰ sulphate in a basin, followed by (1*a*) biological or (1*b*) abiological enrichment in ^{34}S; or (2) introduction of magmatic and/or magmatic-hydrothermal sulphate. In both cases, there is a requirement that the basin be restricted to prevent its dissipation within the sulphate-poor Archaean ocean waters[4].

Option (1*a*) can be largely disregarded since there is a general lack of pyritic graphitic shale in the footwall rocks of the Hemlo succession. Six samples of pyrite from the limited occurrences of graphitic shale have δ^{34}S values ranging from +1.8 to +3.5‰. It is not possible to identify whether options (1*b*) or (2) was dominant. However, a magmatic or magmatic-hydrothermal contribution of sulphate from high-level magma seems possible, considering the intense volcanism in the region[38]; the abundance of high level intrusives, including porphyries; the essential lack of sedimentary rocks in the footwall; and the overall association between sulphates and gold mineralization demonstrated above.

How important might the flux of magmatic and magmatic-hydrothermal sulphate be during the Archaean? The oxidation condition of magmas is thought to have been similar since Archaean time, judging from similar mineral assemblages[39]. Assuming ~900 p.p.m. S in magmas, of which 20% is sulphate, an evaluation may be made of the production rate of magmatic sulphate. At present, the total output of volcanic rocks is estimated to be ~26 to ~34 $km^3 yr^{-1}$, 23 $km^3 yr^{-1}$ in the oceanic environment and 3-10 $km^3 yr^{-1}$ in the continental environment[40]. Using these values, the total amount of sulphate presently produced by submarine magma can be calculated: 23×10^{15} (volume of rocks) × 2.4 (specific gravity) × 900×10^{-6} (content of S) × 0.2 (proportion of SO_4^{2-}) × 96/32 (conversion from S to SO_4^{2-}) = ~3×10^{13} g yr^{-1}. The formation of SO_4 in continental environments is difficult to evaluate because the high rate of SO_2 production from present-day volcanoes, $1.2 \times 96/64 \times 10^{13}$ g $= 1.8 \times 10^{13}$ g (ref. 41) may reflect contamination and assimilation of magma by sulphur-rich sedimentary rocks and because the size of continents in Archaean time is uncertain[42]. If we assume that continental volcanism has been similar throughout geological time, the total production of magmatic sulphate is calculated to be 4.8×10^{13} g yr^{-1}. This compares with ~1.8×10^{14} g yr^{-1} produced by weathering processes[43], so that ~27% of the annual production is magmatic sulphate. Even if we ignore the continental supply, the magmatic sulphate would constitute ~17%.

If magmatic and magmatic-hydrothermal sulphate were to accumulate in the Archaean ocean, the present concentration in sea water, 4×10^{21} g (ref. 43), would have been reached in ~100 Myr. The quantity estimated is a minimum, since volcanism may have been several times more intense at 2,700 Myr (ref. 44) and an undefined quantity of magmatic-hydrothermal sulphate must be added. It can thus be concluded that there was a significant contribution of the magmatic sulphate to the flux of oxidized species in the surface environments in the Archaean and, indeed, in later periods.

Intense volcanism and fast seafloor spreading during the Archaean[42,45] provided a large quantity of reduced mantle material to the Earth's surface. Because of the high rate of interaction between the reduced iron and manganese from the mantle and the hydrosphere at the spreading ridges and subduction zones, the oxidized species formed in the hydrosphere were removed from the Archaean ocean[4,7]. The prevailing reduced conditions in the Earth's surface both in continental and submarine environments was, thus, maintained in Archaean time, and evidence for the presence of sulphate in the hydrosphere, therefore, will be generally lacking. Evidence of magmatic sulphate will only be retained locally in rocks which escaped subduction, such as back-arc basins and rift systems in continents. Preserved continental magmatic-hydrothermal systems, as described above, are other examples.

This study was supported by NSERC grant (grant no: A0616) and the Rector's fund to K.H. We thank Anglo American Corp. of South Africa; Derry, Michener, Booth and Wahl; Lac Minerals; Noranda Mines; Ore Quest Consultants; Pamour Porcupine Mines; Teck Corporation; and Western Mining Corporation for permission to collect samples. We thank R. H. Kirkham for unpublished data, R. W. Sullivan and O. Van Breemen for strontium isotope analyses, and Hitoshi Sakai and Akira Ueda for helpful comments.

Carbon isotope excursions in Precambrian/Cambrian boundary beds, Morocco

Maurice E. Tucker

Department of Geological Sciences, University of Durham, Durham DH1 3LE, UK

The Precambrian/Cambrian boundary is one of the most significant points on the geological timescale, because it marks the change in the fossil record from soft-bodied organisms to skeletonized faunas. The Cambrian explosion or radiation event[1] saw the evolution of many new life forms, especially various molluscs and archaeocyathids from the base of the Cambrian (Tommotian stage). Others, including the trilobites and bivalves, evolved a little later in the succeeding Atdabanian stage[2,3]. A massive increase in the biomass of the photic zone through phytoplankton blooms has also been postulated for this time[4], particularly in the late Riphean/early Vendian and in the early Cambrian[5]. There has been much discussion concerning where precisely to place the boundary[6,7] and there are several contenders in the world for the type section[8]. I present here a carbon isotope profile, from the Precambrian/Cambrian boundary beds in Morocco, where two distinctive positive $\delta^{13}C$ excursions are revealed. These are interpreted as records of increased organic productivity as part of the Precambrian/Cambrian explosion of life. $\delta^{13}C$ excursions could be useful points for correlation between boundary sections.

The late Precambrian/Cambrian strata are extensively exposed on the northern slopes of the Anti-Atlas mountains in southern Morocco[9]. The 'classic' section occurs near the village of Tiout, 25 km south-east of Taroudannt, 80 km east of Agadir (Fig. 1). The sequence begins with the Dolomie Inferieur, 200 m of dolomite with local cryptalgal, grainstone and replaced evaporite horizons. The succeeding Serie Lie de Vin (950 m) consists of cyclically arranged limestones, dolomites and fine clastics which represent rhythmic fluctuations in the position of the shoreline[10]. Algal thrombolites and stromatolites occur throughout the sequence and include the genera *Tungussia*, *Patomia* and *Nimbophyton*[11,12]. The Calcaire Superieur (220 m) consists of massive limestones (some black, some oolitic), dolostones, chert nodules and the stromatolite *Acaciella*. The first trilobites (small opisthoparians[13]) appear towards the top of the Calcaire Superieur, and within a few metres there are archaeocyathid bioherms[14]. The upper, fossiliferous 130 m of the Calcaire Superieur have been separated off to form the Transition Beds[10,12] (Fig. 2). Shales with the trilobite *Fallotaspis* mark the beginning of the Serie Schisto-Calcaire[13], which consists of many transgressive oolite-shale cycles[15]. Overall, the Moroccan sequence reflects mostly shallow-water shelf sedimentation on the subsiding north-west margin of the Saharan Craton, adjacent to the opening Iapetus (Proto-Atlantic) Ocean[16].

There has been much discussion on the position of the Precambrian/Cambrian boundary at Tiout, as at other boundary candidates, but there now appers to be a consensus. On the basis of a detailed study of the stromatolites, notoriously difficult to use for dating, the Serie Lie de Vin is placed in the Vendian (latest Precambrian)[11]. An alternative view on the stromatolites suggests that they are lowest Cambrian[17] but a similar Vendian age for the Lie de Vin is derived from acritarchs[18]. The archaeocyathids indicate a mid-Atdabanian age for the Transition Beds[14], suggesting that the Calcaire Superieur is lower Atdabanian and Tommotian. The Tommotian is recognized by the occurrence of small shelly fossils[1], which are mostly phosphatic, but unfortunately these have not yet been found in the Anti-Atlas despite acid digestion of many samples[11]. The Tommotian stage was generally a regressive time[2] so that its deposits may be thin or even absent. The Precambrian/Cambrian boundary is thus likely to occur in the Lower Calcaire Superieur or Upper Serie Lie de Vin. The Dolomie Inferieur is attributed to the late Riphean[10,18]. A tilloid of probable glacial origin occurs in the Tiddiline Formation, unconformably beneath the Dolomie Inferieur[19].

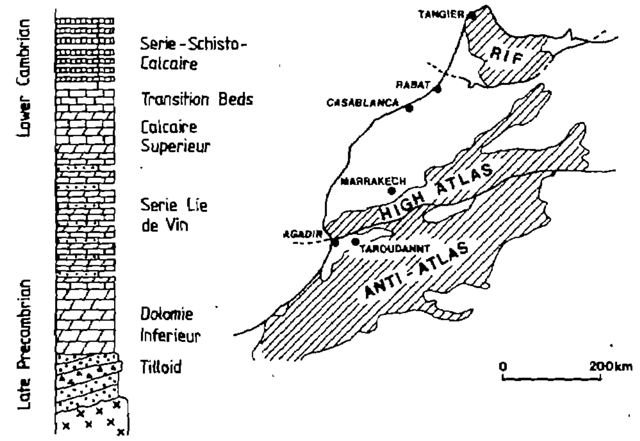

Fig. 1 Location map of Morocco, showing the three principal tectonic units, the Anti-Atlas, High Atlas and Rif, and the stratigraphy of the late Precambrian/Cambrian beds in the Anti-Atlas.

The results of whole-rock, carbon stable-isotope analyses of limestones and dolomites from the Anti-Atlas boundary beds are presented in Fig. 2. With such determinations, there is always the possibility that the values have a diagenetic component through cement precipitation, calcite neomorphism or dolomitization, so that the values do not reflect the isotopic composition of contemporaneous sea water. However, it is generally held that the marine carbon-isotope signature is less prone to alteration during diagenesis than the oxygen isotope as the reservoir of carbon is very much smaller than that of oxygen in diagenetic porewaters[20]. When recrystallization and dolomitization of calcite or aragonite grains and muds take place, in most cases the carbon-isotope ratio is altered little because the carbon atoms are almost entirely derived from the original carbonate.

In organic-rich sediments, diagenetic calcites and dolomites can be very light to quite heavy (-20 to $+10‰ \delta^{13}C$), as a result of the various diagenetic breakdown processes affecting organic matter[21]. However, organic-rich carbonates were not analysed in this study, and in fact, other late Precambrian organic-rich limestones (from Norway[22] and California; unpublished data) analysed have typical marine $\delta^{13}C$ values (average 1.7 and 2.0‰ respectively). Meteoric waters with soil-derived CO_2 can give extreme $\delta^{13}C$ signatures to carbonate precipitates, but these are typically negative, rather than positive, and can be expected to relate to prominent emergence horizons (absent in the Precambrian/Cambrian of the Anti-Atlas). Finally, there is little isotopic fractionation of carbon isotopes with temperature.

The profile in Fig. 2 is derived from limestones and dolomites from a variety of open, shallow-marine facies and degrees of diagenesis, but the broad pattern of $\delta^{13}C$ change is considered to be a genuine record of changes in $\delta^{13}C$ of the original marine precipitates. As an example, there is no significant difference between the $\delta^{13}C$ values of oolites and stromatolites in the Serie Schisto-Calcaire, or between bioclastic and oolitic limestones in the Transition Beds at the top of the Calcaire Superieur. The oxygen-isotope data, not presented here, show more scatter; this is expected as diagenesis can affect the $\delta^{18}O$ considerably, mainly through the precipitation of ^{18}O-depleted calcite spar cement[23], and there can be a several per mil difference between limestones and dolomites. The validity of the very positive $\delta^{13}C$ values of the Dolomie Inferieur might be questioned but, in fact, their oxygen-isotope values (M.E.T., unpublished data) are

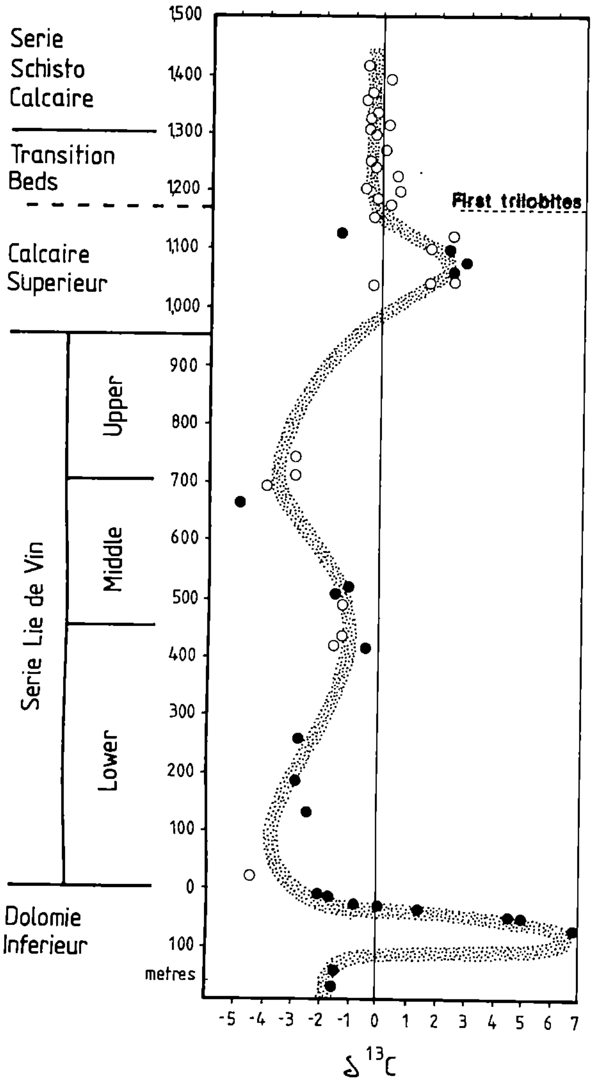

Fig. 2 Carbon-isotope stratigraphy from the late Precambrian/Cambrian boundary beds, Tiout, near Taroudannt, Anti-Atlas. Closed symbols are dolomites; open symbols are limestones.

in the same range (−6 to −9‰ PDB) as the samples above and below, suggesting no major difference in the diagenesis. This deduction is supported by microscopic studies. Thus, the $\delta^{13}C$ isotope profile of Fig. 2 is considered to be a reflection of changes in the carbon-isotopic composition of sea water during the critical late Precambrian/Cambrian time.

The carbon-isotope profile shows two positive excursions in $\delta^{13}C$, one near the top of the Dolomie Inferieur and the other within the Calcaire Superieur. The Serie Lie de Vin has a moderately negative signature, and the limestones of the Transition Beds and Serie Schisto-Calcaire are close to 0‰ PDB. The carbon-isotope signature of marine limestones (and many dolomites) tends to reflect the $\delta^{13}C$ of total dissolved inorganic carbon (TDC) in sea water. Average oceanic $\delta^{13}C$ TDC today is ~0‰ and shallow marine carbonate precipitates are in the range 0 to 4‰ PDB (refs 20, 23). Organic carbon, on the other hand, has very negative $\delta^{13}C$, in the range −20 to −30‰, since the lighter ^{12}C is preferentially incorporated into organic matter. It is generally assumed that the input of carbon to the oceans has remained relatively constant through time and that the ocean carbon reservoir mass had changed little. Changes in oceanic $\delta^{13}C$ TDC are thus thought to be caused by variations in the carbon output to the organic carbon (C_{org}) and carbonate carbon (C_{carb}) reservoirs[24,25]. At present, a C_{org}/C_{carb} output ratio of around 1:4 maintains the steady-state $\delta^{13}C$ of ~0‰ in oceanic water. Increases in the burial rate of the ^{12}C-enriched organic carbon, relative to the amount of carbonate carbon being precipitated, thus lead to a positive or heavier isotopic composition of seawater TDC, and of carbonate precipitates therefrom. Higher rates of organic carbon burial could result from increases in organic productivity. Alternatively, they could reflect an increase in the preservation potential of the organic carbon; this could result from oceanographic effects, such as the development or expansion of oxygen-depleted oceanic water masses. Positive excursions of $\delta^{13}C$ have been detected in Cretaceous and Jurassic limestones[26,27], and correlate with oceanic anoxic events (OAEs), when increased organic productivity through eustatic sea-level rises leads to the burial of much organic matter and depletion of the oceanic TDC in ^{12}C.

The two positive $\delta^{13}C$ excursions revealed in the Morocco boundary beds can be interpreted as indicating increased levels of organic productivity, resulting in the preferential extraction of ^{12}C from the oceanic carbonate reservoir. The excursion at the top of the Dolomie Inferieur is probably close to the Riphean/Vendian boundary, a time of radiation of eukaryotic plankton[5]; it could reflect a major increase in the microplankton in the oceans, perhaps an evolutionary event related to a post-glacial climatic warming or more vigorous oceanic circulation connected with the opening of Iapetus, which took place around this time[16]. There are no major facies changes through the peritidal Dolomie Inferieur, so that the $\delta^{13}C$ event is unlikely to reflect increased productivity through a eustatic sea-level rise, as is generally the case with the Cretaceous OAEs[28]. The Dolomie Inferieur is not particularly organic-rich but the organic matter would probably be buried in deeper water sediments of contemporaneous basins and oceans. Such organic-rich deposits occur in the early Vendian of the Sparagmite Basin, south Norway[22]. The second positive excursion, in the Calcaire Superieur, is not so extreme but occurs in strata probably containing the Tommotian/Atdabanian boundary. This was a time of rapid metazoan evolution[1,2] and a second radiation event of the microplankton[5]. These increased levels of organic productivity can be expected to have affected the oceanic carbon budget. After each $\delta^{13}C$ excursion, the sea water returned to more normal values as recycling of the organic matter restored the balance of the organic carbon/carbonate carbon reservoirs.

The late Precambrian/early Cambrian was a time of oceanic chemical events. An extreme rise in the sulphur-isotope ($\delta^{34}S$) curve has been termed the Yudomski Event[29] and attributed to the catastrophic mixing of brine in local basins with the surface ocean water. An OAE and a phosphogenic event have been postulated for this time[4], along with catastrophic mixing of deep anoxic waters with aerated surface waters[4,30]. These chemical events have been invoked as major factors in organic evolution (as well as extinction), and they can be expected to have had an effect on the carbon-isotopic signature of sea water. It is possible that the $\delta^{13}C$ excursions reported here are connected with the other chemical events which took place around the Precambrian/Cambrian boundary and which were probably instrumental in the Cambrian metazoan radiation event.

If, as contended, the $\delta^{13}C$ excursions reported here are due to fluctuations in oceanic $\delta^{13}C$, they should be recorded in other boundary sections and could be a means of correlation, independent of the palaeontology, in a similar way to that proposed for magnetic polarity stratigraphy[31]. This could be very useful with some boundary profiles where, because of the facies developed, fossils are poorly represented.

This project is supported by the NERC. I thank John Rouse, formerly of the British Geological Survey, for organizing the isotope analyses; the Ministère de l'Energie et des Mines, Rabat, for permission to undertake fieldwork in Morocco; Martin Brasier, John Cowie, John Hudson, John Rouse, Mike Arthur and Phil Sandberg for comments; and Andy for artwork, and Nicola for wordprocessing.

Planktonic foraminiferal ontogeny and new perspectives for micropalaeontology

Geert-Jan A. Brummer*, Christoph Hemleben† & Michael Spindler‡

Planktonic foraminifers are some of the most widely used microfossils for dating marine sedimentary rocks and the calcareous test has been used to reconstruct their depositional history over the past 120 million years[1]. By tracing the successive growth stages of extant representatives of this group, we have obtained criteria which identify pre-adult forms that, traditionally, have been disregarded in foraminiferal research. Thus, large quantities of "... unidentifiable miscellaneous juveniles ..."[2] have become available to help decipher the fossil record of marine environments. Comparative studies of growth series at species and supraspecific levels allowed the identification of three major species groups, each showing three different developmental stages. Their recognition introduces new possibilities for establishing a natural classification of planktonic foraminifers, for disclosing their evolutionary history and for testing evolutionary models in general.

Despite the early recognition of the importance of reconstructing the sequence of events during planktonic foraminiferal growth[3-8], only recently has the first comprehensive and comparative work appeared[9]. Departing from previous procedures, we followed an ontogenetic approach by considering the complete series of individual ontogenetic stages of each of the 10 species present in our samples. We used pre-adult tests collected from the living plankton offshore Barbados to minimize interference by additional carbonate layers secreted during later growth stages[7], and to exclude post-lifetime alterations of the test[1].

Initially, the pre-adult morphology of a species had to be learned by backtracking the successive growth stages of transparent adult specimens under the light microscope (Fig. 1*c*, *d*). This enabled us to determine the taxonomic identity of the individual pre-adult stages and to reverse the backtracking process in order to document morphological change during ontogeny.

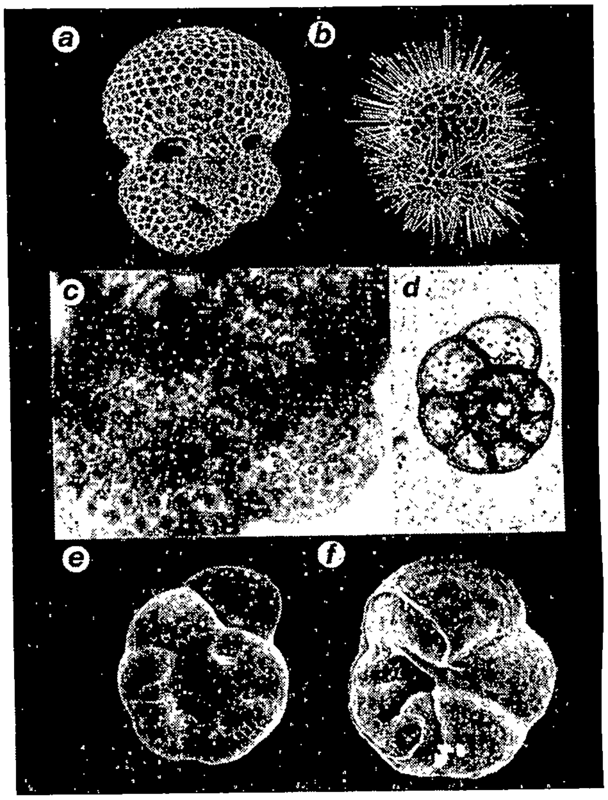

Fig. 1 Scanning electron (*a*, *b*, *e*, *f*) and transmission light (*c*, *d*) micrographs, illustrating the pre-adult morphology of *G. sacculifer* (Brady) as obtained from backtracking the successive growth stages of transparent adult specimens. *a*, Spiral view of adult specimen (×88). *b*, Umbilical view of adult specimen (×79). *c*, Same specimen as in *a*, showing the pre-adult growth stages contained in the adult test (×194). *d*, Spiral view of a typical juvenile (×321). *e*, Spiral view of a juvenile, compare with *c* and *d* (×429). *f*, Umbilical view of an early neanic form, showing the abrupt morphological transition from the juvenile stage (penultimate chamber) to the neanic stage (last chamber; ×352).

Most species completed at least three phases of growth. During the initial (juvenile) stage, as well as the final (adult) stage, growth is morphologically conservative. Confined by rather spasmodic morphological changes, the intermediate (neanic) stage shows rapid transformation of virtually all features during its development.

Three species groups exhibiting characteristic ontogenetic morphology could be discerned (Fig. 2). Their distinction is essentially based on the same criteria used in traditional foraminiferal classification: gross shape of the test and constituent chambers, presence or absence of spines, position of the aperture(s) and texture of the test wall[10]. Remarkably the species groups distinguished here coincide with a subdivision in adult wall-textural types as conceived recently[11].

Group 1, comprising the species *Globigerinella aequilateralis* (Brady), *Globigerinoides conglobatus* (Brady), *Globigerinoides ruber* (d'Orbigny), *Globigerinoides sacculifer* (Brady) and *Orbulina universa* (d'Orbigny), shows striking morphological changes during ontogeny (Fig. 2*a*-*d*). Juveniles of this group have few large pores concentrated along sutures, a smooth test wall with sparse, sparsely distributed delicate spines and an extra-umbilical aperture. Then, when a size of ~80 μm is reached, abrupt morphological changes occur, marking the onset of the neanic stage. Well-defined, densely distributed spines appear on all chambers, pores spread over the entire chamber surface and the cancellate wall texture emerges (Fig. 1*f*). During the neanic phase, the number of chambers per whorl decreases and the main aperture shifts towards its ultimate position. Finally, at a size of ~200 μm, advanced features such as secondary apertures herald the transition from the neanic to the adult stage of growth.

Group 2, which includes the species *Globorotalia menardii* (Parker, Jones and Brady) and *Neogloboquadrina dutertrei* (d'Orbigny), ontogenetically resembles group 1 (Fig. 2*e*–*h*). Consistent differences are the pustulate instead of spinose wall texture, the less-pronounced apertural shift during the neanic stage and a morphologically gradual neanic–adult transition. Additional characteristics of *G. menardii* comprise the development of a keel during the neanic stage and the absence of a cancellate wall texture.

Group 3, consisting of *Candeina nitida* (d'Orbigny), *Globigerinita glutinata* (Egger) and *Globigerinita juvenilis* (Bolli), retains most morphological features throughout ontogeny (Fig. 2*i*–*l*). Numerous minute pores may cover the non-spinose, pustulate test from as early as the second chamber. The apertural shift is a prominent feature of the neanic stage but the neanic–adult transition could be defined only in *C. nitida*, where chambers provided with numerous sutural apertures cover the umbilicus.

Planktonic foraminiferal classification, taxonomy and phylogeny has relied solely on adult morphological features[9–12]. Our study of growth series of species reveals that major taxonomic characters change during the ontogeny of individual species. If the present, adult-based taxonomy were applied to the successive ontogenetic stages of, for instance *G. ruber*, it would have to be assigned to three different genera. As integral

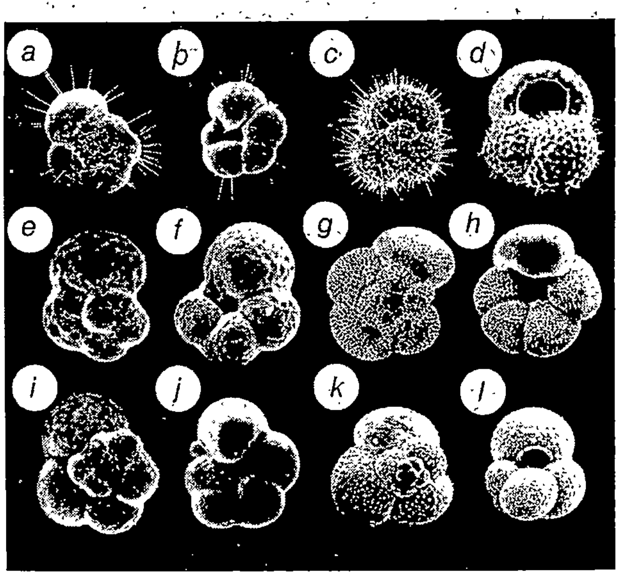

Fig. 2 Scanning electron micrographs of the adult versus pre-adult morphology of three species representing the three species groups distinguished by their ontogeny. *a*–*d*, *G. ruber* (group 1); *a*, *b*, spiral (×449) and umbilical (×469) view of juvenile, *c*, *d*, same views (×120, ×147) of adult specimens. *e*–*h*, *N. dutertrei* (group 2); *e*, *f*, spiral (×290) and umbilical (×304) view of early neanic forms, *g*, *h*, same views (×74, ×62) of adult specimens. *i*–*l*, *G. juvenilis* (group 3); *i*, *j*, spiral (×653) and umbilical (×805) view of early juvenile, *k*, *l*, same views (×143, ×136) of adult specimens. Striking differences between ontogenetic phases are observed, involving taxonomically important characteristics such as wall texture, spine and pore distribution, shape and number of chambers in the last whorl, and position of the aperture.

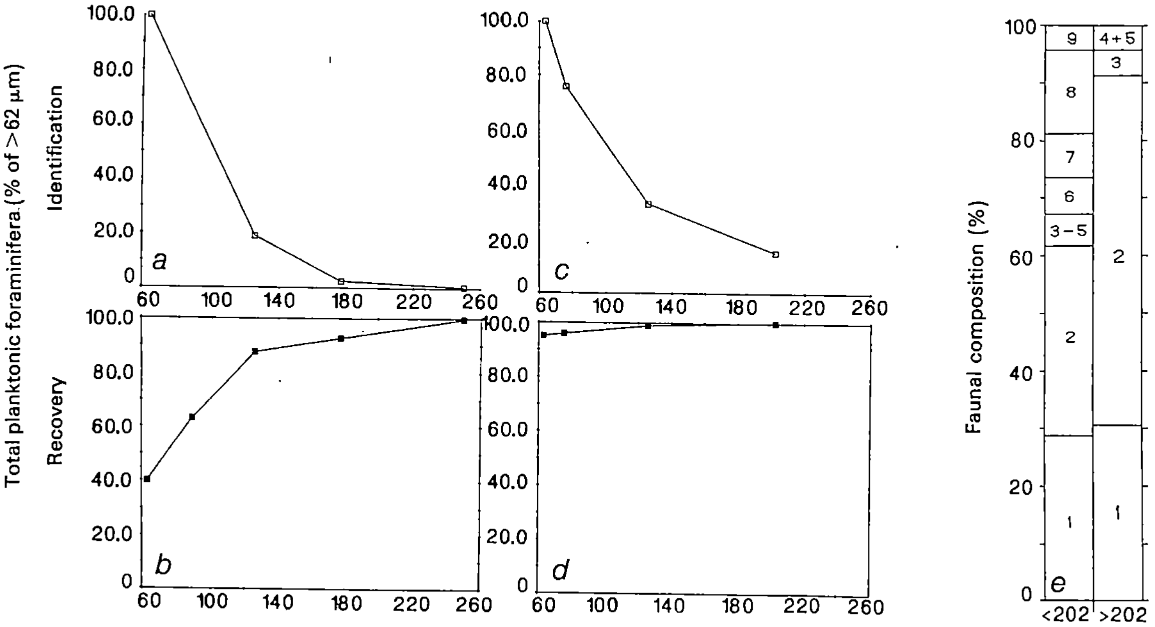

Fig. 3 Effect of the ontogenetic analytical approach on recovery, identification and species composition of planktonic foraminifers in relation to sieve mesh size. Sediment sample preparation methods traditionally use 125-μm or larger-sized sieve mesh fractions[2]. Living plankton is usually collected by plankton nets of 202 μm or greater mesh size[16]. *a*, Recovery in sediment surface samples from the Santa Barbara Basin, Pacific Ocean, demonstrating the exponential growth of the recovery of specimens with decreasing mesh-size (after ref. 16). *b*, Single sediment surface sample from offshore Madagascar, Indian Ocean, showing rapidly diminishing identification frequencies towards the fine fractions when conventional identification criteria are used (modified after ref. 2). *c*, Surface water, 10-μm plankton net samples from offshore Barbados, Caribbean Sea. Recovery frequency runs parallel to that of sediment surface samples in *a*. *d*, Same sample as in *c*, using identification criteria based on ontogenetic morphology. The identification frequency remains very high in contrast to low values attained by using conventional (adult) morphological criteria (*b*). *e*, Changed species composition in the >202-μm compared with the <202-μm sieve fraction of a 10-μm plankton net sample (same as in *c*, *d*). 1, *G. ruber*; 2, *G. sacculifer*; 3, *N. dutertrei*; 4, *Globigerinella aequilateralis*; 5, *O. universa*; 6, *Globorotalia anfracta*, 7, *Globigerinita glutinata*; 8, *G. juvenilis*; 9, unidentified. Note the absence of *G. anfracta*, *G. glutinata* and *G. juvenilis* in the >202-μm fraction and the greatly reduced relative frequency of *G. sacculifer* in the <202-μm fraction.

parts of ontogeny, the morphology of the juvenile, neanic and adult phases together provide a new and comprehensive set of distinguishing features, evoking a reconsideration of our theory about planktonic foraminiferal species.

Although phylogeny has essentially been considered as a series of ontogenies[13,14], the comparison of adult morphological characteristics has traditionally been used to reconstruct planktonic foraminiferal evolutionary lineages[9,12]. We expect that comparative ontogeny, rather than adult morphology alone, will produce a balanced and natural classification, taxonomy and phylogeny[1,3] which, at present, suffers from adaptive adult morphological convergences and repetitive evolution[1,12]. Using comparative ontogeny to infer evolutionary lineages reliably, we can more accurately define lineage-zones, regarded as "... one of the best assurancies of reliable time correlation on a biostratigraphic basis"[15].

Most importantly, ontogenetic morphology allows the identification of the pre-adult forms which constitute the bulk of a foraminiferal sample[2,16]. The 125-μm, 149-μm or 202-μm sieves generally used to recover adult forms also induce the single most critical artefact in faunal analyses[2]. With decreasing mesh size, recovery of specimens from a sample increases exponentially, identification frequencies decline correspondingly and marked shifts in faunal composition occur (Fig. 3). A pilot survey of a 10-μm plankton net sample from offshore Barbados shows an exponentially increasing specimen recovery, similar to that reported elsewhere[2,16]. However, when ontogenetic morphology is used as a tool for identification, 95% of the small (62–125 μm) sieve-size fraction is still identifiable (Fig. 3*d*). Faunal analysis of the same sample shows marked changes in species composition relative to sieve mesh size (Fig. 3*e*). Large species dominating the >202-μm fraction have greatly diminished relative frequencies in the <202-μm fraction, whereas small species start to appear in considerable quantities.

Small species, accounting for about one-third of all extant taxa[1], have a largely unexplored potential due to their hidden occurrence among unidentified pre-adult forms. Together, their abundance and great diversity may give a detailed biostratigraphical analysis of fossil, adult-poor, shallow marine sediments. Faunal composition, as recognized in the small-sized fraction, will lead to more accurate and stable reconstructions of late Tertiary palaeoceanography and palaeoclimatology[16], which rely mainly on patterns of foraminiferal distribution[1].

Planktonic foraminiferal ontogeny yields a new and penetrating micropalaeontological approach which will contribute towards a better understanding of planktonic foraminifers as a group and their application in biostratigraphy, palaeoceanography and palaeoclimatology.

Acoustic cavitation generated by microsecond pulses of ultrasound

L. A. Crum* & J. B. Fowlkes

Physical Acoustics Research Laboratory, Department of
Physics and Astronomy, University of Mississippi, Oxford,
Mississippi 38677, USA

Under extreme acoustic stress, liquids can be caused to rupture, with the transient generation of a vapour cavity. The subsequent collapse of these cavities is normally violent enough to be observed with the unaided eye or ear, and often generates free radicals due to the high temperatures and pressures associated with the collapse. Flynn[1] has calculated that microsecond pulses of ultrasound with peak intensities in the range 10–30 W cm^{-2} can generate transient cavitation in water. Because some diagnostic ultrasound systems[2,3] now in clinical use generate microsecond length pulses with temporal peak intensities >100 W cm^{-2}, there is reason to believe that this mechanism could operate in diagnostic conditions in aqueous media. We show here that ultrasonic pulses as short as one cycle at a frequency of 1.0 MHz give rise to luminescence flashes characteristic of violent cavitation. This provides the first experimental confirmation of Flynn's theoretical calculations.

Because the pulses produced by diagnostic ultrasound generators are rich in harmonics and short in time, we decided not to utilize the commonly used cavitation detection criterion—the acoustic detection of a shock wave or subharmonic frequency components—as there is little evidence that cavitation collapses in this short pulse regime can be detected acoustically. Rather, we have used a photometric detection system based on the observation, through a photomultiplier tube, of light produced by the cavitation bubble. This light emission results from the oxidation of luminol by the free radicals generated during the collapse of a cavity and should properly be termed chemiluminescence.

An essential ingredient of the cavitation generation system is that the acoustic pressure amplitude of the sound field is increased linearly with time, at a reproducible rate, until cavitation occurs. The experimental system will be described in more detail in a later report, a similar apparatus is described elsewhere[4]. The heart of the system is a ramp generator that drives both a strip recorder and the amplitude modulation input of a function generator. The d.c. voltage level on the strip chart record is linearly related to the peak-to-peak output of the function generator. This signal is amplified and delivered to a focused transducer (resonance frequency 1.0 MHz) that radiates into an echo-free chamber (wall lined with acoustic absorber) filled with distilled water saturated with argon, and containing luminol. The chart record is calibrated in units of megapascals by inserting a small, calibrated hydrophone (Medicoteknisk Institut, PVDF ultrasonic probe, outer diameter, 1.0 mm) into the focal region of the sound field during simulated measurements at low amplitudes.

Light generated by a cavity collapsing in the focal region is detected by a photomultiplier tube and the resulting pulse is preamplified and fed into a pulse height discriminator. The

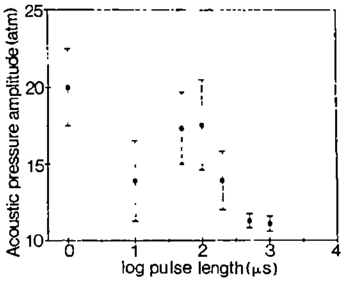

Fig. 1 Variation of the acoustic cavitation threshold of water containing luminol with pulse length for a duty cycle of 1:10. The points are the average of at least 10 independent measurements and the error bars represent ± one standard deviation. The carrier frequency was 1.0 MHz and the liquid was saturated with argon. The abscissa plots the logarithm (to the base 10) of the pulse length to compress the scale. Thus, an abscissa value of 3 implies that about 1,000 cycles were contained in the pulse, 2 means 100, 1 means 10, and 0 indicates that the pulse contained essentially one cycle.

discriminator level determines the sensitivity of the apparatus and is set to 600 mV, which is well above the average electrical background level (~150 mV) but below the typical chemiluminescence pulse height (~1.0 V). After discrimination, the signal passes through a noise gating network that either ignores the signal (no decision) or resets the system (cavitation detected). The noise gating network is a type of coincidence counter that requires that two pulses be observed within a 100-ms time interval. The reason for this criterion is that we have discovered through experience that a cavitation 'event' typically generates several optical flashes during 100 ms while the background noise is randomly distributed in time. The noise gating thus significantly lowers the false count rate. The system is reset by an immediate reduction of the acoustic pressure amplitude to zero for a quiescent period of 300 s; after this resting period is over, the acoustic pressure is again ramped until a cavitation event occurs and the sequence is repeated.

We have taken measurements of the cavitation threshold as a function of pulse length and of the length of time between pulses (duty cycle). A duty cycle of 1:10 means that the sound field is on for 1 time unit and off for the succeeding 9 time units. (This is a much longer duty cycle than used clinically by one to two orders of magnitude.)

Figure 1 shows the measured values of the threshold acoustic pressure amplitude required to initiate cavitation in distilled water containing luminol, as a function of pulse length, with a duty cycle of 1:10. Similar behaviour is observed for duty cycles of 1:3, 1:5 and 1:20. It is the temporal peak acoustic pressure rather than the average intensity that is important in the generation of cavitation effects[5]. An approximate value of the temporal peak intensity can be obtained by assuming a plane wave and using the relation $I = P_a^2/2\rho c$, where P_a is the temporal peak acoustic pressure, ρ is the density of the liquid and c the velocity of sound in the liquid.

Each data point presented is the average of at least 10 individual measurements. For the critical data point at an abscissa value of 0 (corresponding to pulses generated by a diagnostic ultrasound generator), we have taken more than 30 separate measurements on three different days with three different liquid samples. On one occasion, a second operator made the measurements (although the system is essentially automated). We thus have confidence in the validity of this measurement. Furthermore, at a duty cycle of 1:10, and at values of the temporal peak acoustic pressure only slightly higher than that determined as the threshold, single cycle pulses of 1-MHz ultrasound give light emission that is easily visible to the naked eye.

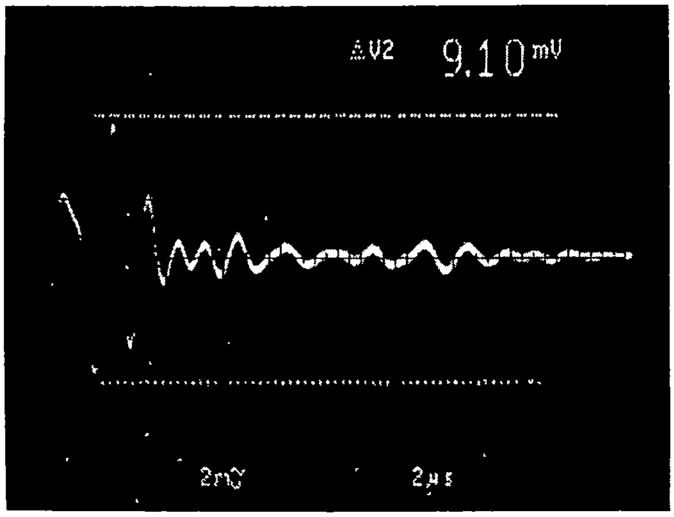

Fig. 2 An oscilloscope photograph of the temporal variation of the acoustic pressure near the focus of the sound field as measured by a calibrated miniature hydrophone. This pulse is intended to mimic those used in diagnostic ultrasound scanners.

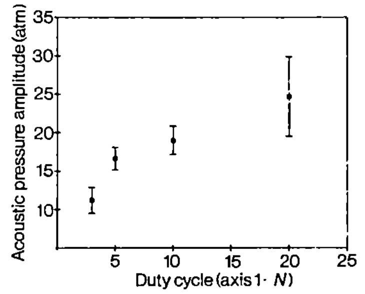

Fig. 3 Variation of the acoustic cavitation threshold of water containing luminol with duty cycle for a pulse length of ~1μs. The carrier frequency was 1.0 MHz and the liquid was saturated with argon.

Figure 2 shows a photograph of the temporal variation of the acoustic pressure as measured by our miniature probe hydrophone. Note that there is some ringing of the transducer but only at a much reduced amplitude. This pulse closely resembles the scanning mode pulse of a diagnostic ultrasound system which typically has a large negative cycle followed by a large positive cycle. Furthermore, this pulse is also similar to that used by Flynn[1] in his theoretical studies.

We have also examined the dependence of the cavitation threshold on duty cycle for the 'one cycle' pulse. These data are shown in Fig. 3. We have been concerned that the cavitation nuclei may respond to the pulse repetition frequency rather than the individual pulses. However, since the acoustic pulse used here dies out within a few microseconds, (well before the beginning of the next pulse), there is good reason to believe that these pulses act independently of each other. The data in Fig. 3 essentially confirm this fact showing an asymptotic behaviour at larger duty cycles. Furthermore, Marston and Unger[6] have presented evidence that single pulses of negative pressure can produce cavitation in water.

Note that we have established an arbitrary definition of the cavitation threshold as that value of the peak temporal acoustic pressure at which the output pulses reaching the pulse height discriminator from the photomultiplier tube have values of 600 mV or larger. This requirement is a working definition in that this discriminator setting permits us to obtain a desirable signal-to-noise ratio. It is quite conceivable that a more sensitive detection system would indicate lower values of the threshold. Our definition of cavitation involves the production of light by the collapsing cavity. Sonoluminescence is a reasonably well understood phenomenon[7,8] that is apparently the result of the radiative recombination of free radicals produced by the collapsing cavity[9]. However, the light emission that we observe is probably not sonoluminescence from within the cavity itself (produced by the recombination of free radicals); rather, it is light from the bulk of the liquid resulting from free radicals which 'escape' from the cavity and react with the luminol. Luminol has been used by several researchers (see, for example, ref. 10) to increase the output of light emissions from acoustic cavitation and the specific oxidation reactions that lead to light emission have been studied in some detail[11,12]. What is most important, and relevant to this work, is that the presence of free radicals are required for light emission to occur. Because these free radicals are highly reactive, and pose a threat to biological tissues, it is their presence that is important, not the light emission *per se*.

The light emission from the insonified area we observed can be seen by the naked eye, and appears in the form of 'streaks' rather than 'flashes'. We interpret this as being due to the relatively long lifetime of the oxidation reaction (as long as 50 ms according to Finch[10] and the rapid movement of collapsing cavities through the focal region due to radiation pressure forces. However, we have recently observed intense light emission from a form of 'stable' cavitation, in which bubbles pulsate violently for many cycles, with the use of an image intensifier tube as a light detector[13]. Because the temporal peak acoustic pressures are quite large, we should not expect that individual cavitation bubbles would survive the collapse phase and remain intact. It is possible, however, that the collapse and bubble breakup would effectively 'seed' the liquid with several new microbubbles that could act as cavitation nuclei[14]. The nearly continuous light emission suggests this form of 'steady' cavitation.

Finally, we draw attention to the fact that biological systems possess stabilized gas nuclei that can be activated by reduced pressures, either statically, as in the case of decompression sickness[15,16], or dynamically, as in the case of the biological effects of ultrasound[17–21]. These nuclei seem to exist in appreciable numbers in a variety of biological tissues, and our new evidence gives reason to believe that single cycle pulses of ultrasound could activate these nuclei in a violent manner. Accordingly, the data presented here may have important implications for clinical use of such ultrasound systems and imply that extensive risk assessment studies ought to be carried out.

Potent ulcerogenic actions of platelet-activating factor on the stomach

Ann-Charlotte Rosam, John L. Wallace & Brendan J. R. Whittle

Department of Mediator Pharmacology,
Wellcome Research Laboratories, Beckenham, Kent BR3 3BS, UK

Platelet-activating factor (PAF) is an endogenous phospholipid which has been implicated as a mediator of allergic and inflammatory processes[1]. It is synthesized and released by neutrophils, platelets, macrophages, monocytes, basophils and endothelial cells[2–8], and is a potent platelet-aggregating agent, a vasodilator, increases vascular permeability, stimulates neutrophil aggregation and degranulation[9] and induces release of lysosomal enzymes[10]. A role for PAF in the hypotension associated with endotoxin shock[11,12] and in necrotizing enterocolitis[13] has recently been suggested. As there is an association between septic shock and acute gastric damage[14], we propose that PAF is an endogenous mediator of ulceration in the stomach. Indeed, as reported here, intravenous (i.v.) infusion of PAF to rats, at doses of 20–200 pmol per kg per min, resulted in the formation of extensive haemorrhagic erosions in the gastric mucosa. The ulcerogenic actions of PAF are not attributable solely to its hypotensive actions and were not mediated via effects on platelets or cyclooxygenase products, nor via histamine H_1, H_2 or α-adrenergic receptors. PAF is the most potent gastric ulcerogen yet described and its endogenous release may underlie or contribute to certain forms of gastric ulceration.

PAF (1-*O*-alkyl-2-*O*-acetyl-*sn*-glyceryl-3-phosphorylcholine; Sigma) was infused i.v. (100 ng per kg per min) to pentobarbitone-anaesthetized male Wistar rats for periods of 5–20 min. The stomachs were removed immediately after the PAF infusion or at 30–180 min after the infusion. With this dose, macroscopically visible gastric erosions were present in all of the treatment groups. As the most consistent level of damage was produced in the group infused with PAF for 20 min with the stomach removed 60 min later, this protocol was used in all subsequent experiments. To test the relationship between dose of PAF and the extent of gastric damage, PAF was infused i.v. at doses of 10–100 ng per kg per min (20–200 pmol per kg per min); 1 h later the stomachs were removed, opened and the mucosa was photographed using colour transparency film. Samples from the fundic region were fixed in neutral-buffered formalin for subsequent histological analysis. The severity of macroscopically visible damage was scored, independently, by two observers in a randomized, blind manner and assigned a score on a scale from 0 (normal) to 3 (severe) (see Fig. 1 legend).

All doses of PAF produced areas of macroscopically visible gastric hyperaemia, with doses of 30–100 ng per kg per min producing extensive, severe hyperaemia and haemorrhage (Fig. 1). As evaluated histologically, the damage caused by these doses of PAF was characterized by extensive vascular congestion, extravasation of erythrocytes, destruction of the surface epithelium, dilatation of glands and focal regions of necrosis extending throughout the depth of the mucosa (Fig. 2). The incidence of these effects increased with an increase of the dose of PAF infused. In addition to congestion of mucosal and submucosal blood vessels with erythrocytes, aggregates of polymorphonuclear leukocytes were frequently observed, particularly at the base of the mucosal glands.

As has been reported previously[9], infusion of PAF had significant dose-related hypotensive effects. At doses of 10, 30, 50 and 100 ng per kg per min, PAF produced decreases in mean systemic arterial blood pressure of 18±4, 48±4, 62±4 and 64±9 mm Hg, respectively ($n = 5$ per group). Although it is well established that both clinical and experimental shock are associated with acute gastric ulceration[15], a reduction in blood pressure

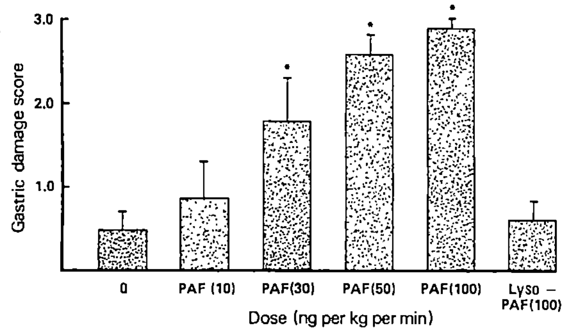

Fig. 1 Gastric damage scores for rats given PAF, lyso-PAF or vehicle alone i.v. for 20 min. Damage was assessed from colour transparencies taken 1 h after completion of the infusion. A score of 0 was assigned if the mucosa appeared normal. A stomach exhibiting haemorrhage or erythaema was assigned a score of 1 (diffuse), 2 (moderate, multiple sites) or 3 (severe, extensive). The scoring was done independently by two observers in a randomized, blind manner and there was a highly significant correlation ($r = 0.87$; $P < 0.001$) between the scores assigned by the two observers. Asterisks indicate groups which differ significantly ($P < 0.05$) from the control group.

Table 1 Effects of hypotensive agents on gastric mucosal damage

Compound	Dose (μg per kg per min)	Damage score	% With haemorrhage	Δ *BP* (mm Hg)
Vehicle	—	0.5 ± 0.2	0	1 ± 2
PAF	0.05	2.6 ± 0.2*	75	62 ± 4*
Prostacyclin	0.5	0.6 ± 0.2	0	55 ± 4*
Isoprenaline	0.5	0.3 ± 0.2	0	50 ± 3*
Nitroprusside	10.0	1.4 ± 0.4†	0	72 ± 2*

Hypotensive agents were administered i.v. for 20 min; 1 h after completion of the infusion, the stomach was removed and the damage assessed as described in Fig. 1 legend. The presence of haemorrhage was determined histologically and is expressed here as the per cent of the total number of rats in which haemorrhage was observed. In the control group, vehicle (0.25% bovine serum albumin in normal saline) alone was infused. Isoprenaline hydrochloride (Sigma) and sodium nitroprusside (BDH) were dissolved in normal saline. Prostacyclin (Wellcome Foundation Ltd) was dissolved initially in 1 M Tris buffer (*p*H 8.5) then diluted in 1.25% sodium bicarbonate. Results are the mean ±s.e.m. for 5–8 rats per group. Δ *BP* represents the decrease in mean arterial blood pressure during the infusion of the compound. With all agents, the peak fall in blood pressure was observed within 1 min of the start of the infusion and the depression of blood pressure was maintained throughout the infusion period. After termination of the infusion, the blood pressure returned to control levels within 10 min.

* $P < 0.01$; † $P < 0.05$, significant difference compared with the control group.

by pharmacological vasodilators is not generally associated with such mucosal damage. However, to determine whether the fall in blood pressure produced by PAF was itself sufficient to induce gastric damage in the present study, some other hypotensive agents were administered i.v. according to the same protocol. Isoprenaline (0.5 μg per kg per min), prostacyclin (0.5 μg per kg per min) and nitroprusside (10 μg per kg per min) each produced a rapid fall in blood pressure of 50–70 mm Hg which was comparable to that induced by high doses of PAF and was maintained throughout the period of infusion (Table 1). Only infusion of nitroprusside produced macroscopic gastric damage, but this was significantly less severe ($P < 0.05$) than that produced by a dose of PAF (30 ng per kg per min) which elicited a significantly smaller ($P < 0.05$) fall in blood pressure. Furthermore, histological evaluation revealed that none of these hypotensive agents produced haemorrhagic erosions in the gastric mucosa. Thus, the fall in blood pressure induced by PAF would be insufficient alone to produce the observed mucosal damage.

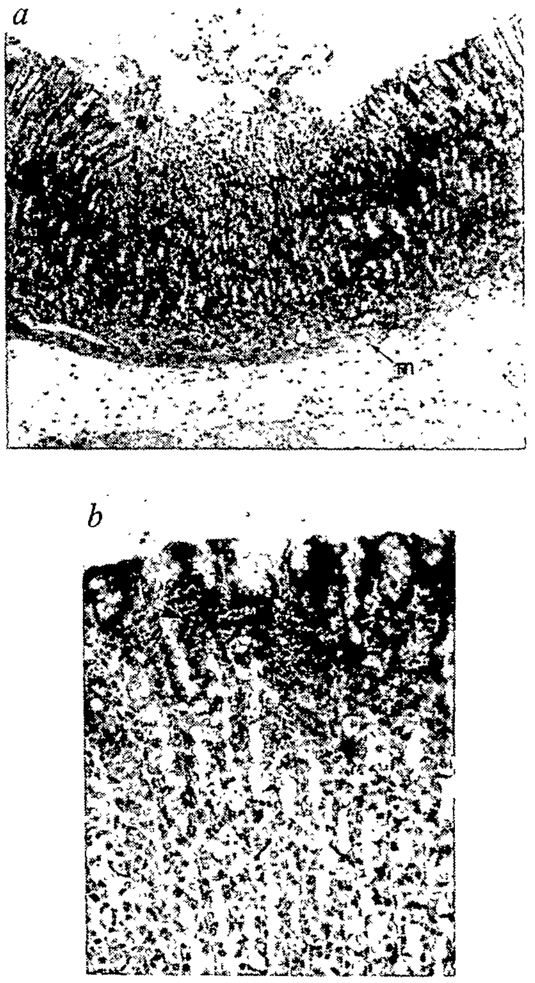

Fig. 2 *a*, Haemorrhagic erosion in the gastric mucosa of a rat given PAF (100 ng per kg per min) for 20 min. The tissue was fixed 1 h after completion of the infusion. Note that the necrotic region extends down to half the depth of the mucosa and does not penetrate the muscularis mucosae (m). Extruded cells (e) can be seen in the lumen. (Haematoxylin and eosin stain. ×39.) *b*, Mucosal vasocongestion (arrows) in gastric mucosa of rat given PAF as for *a*. This engorgement extended throughout the entire depth of the mucosa. Macroscopically, this region appeared hyperaemic. (Haematoxylin and eosin stain. ×96.)

We investigated whether the effects of PAF are shared by its structurally similar precursor and breakdown product, lyso-PAF (1-*O*-alkyl-*sn*-glyceryl-3-phosphorylcholine). Lyso-PAF (100 ng per kg per min) given i.v. had no significant effect on the gastric mucosa, as assessed either macroscopically (mean score of 0.6 ± 0.2) or histologically, nor did it affect blood pressure. A higher dose of lyso-PAF (10 μg per kg per min), which also failed to alter the blood pressure, produced diffuse mucosal hyperaemia (mean score of 1.4 ± 0.3). The level of damage was less than that produced by PAF at 30 ng per kg per min, indicating a difference in ulcerogenic potency of over 3,000-fold, while a dissociation between the gastric-damaging actions and any hypotensive actions of lyso-PAF was clearly demonstrated.

Although PAF has been shown to be a vasodilator in most organs and to increase vascular permeability, its actions on the gastric vasculature are not yet known. Histamine, a vasodilator, has been suggested to have pro-ulcerogenic actions[16], perhaps through its ability to increase capillary permeability. Several agents which have vasconstrictor actions in the gastric mucosa have also been shown to be pro-ulcerogenic: for example, thromboxane A_2 (ref. 17) and noradrenaline[18]. Release of these endogeneous mediators could, therefore, be involved in the ulcerogenic actions of PAF. To test for any such role, an inhibitor of cyclooxygenase (indomethacin), an α-adrenergic receptor antagonist (phentolamine) or a histamine H_1-receptor antagonist (mepyramine) was administered before i.v. infusion of PAF (50 ng per kg per min) at a dose yielding a damage score of 2.6 ± 0.2. Indomethacin (5 mg per kg subcutaneous) administered 45 min before PAF caused a significant ($P < 0.001$) increase in the damage score (3.0 ± 0; $n = 4$). Pretreatment with phentolamine (10 mg per kg i.v.) or mepyramine (5 mg per kg i.p.) did not significantly affect the extent of damage induced by PAF (mean score 2.0 ± 0.2, $n = 5$ and 2.0 ± 0, $n = 3$, respectively). The ulcerogenic actions of PAF therefore appear to be independent of the release of these mediators.

Although resting gastric acid secretion in the anaesthetized rat is low, intragastric instillation of 0.1 M HCl (3 ml) before PAF infusion (50 ng per kg per min) did not significantly augment the severity of macroscopic damage, although the regions of mucosal haemorrhage were stained black. Furthermore, i.v. administration of antisecretory doses of the H_2-receptor antagonist cimetidine (50 mg per kg) 15 min before infusion of PAF (100 ng per kg per min) did not significantly reduce the severity of the gastric damage (mean score of 2.8 ± 0.3; $n = 4$). Thus, unlike the case with many experimental models of gastric damage, the presence of a high intraluminal concentration of acid is not a prerequisite for PAF-induced ulceration.

Despite its name, PAF does not cause platelet aggregation in the rat, nor does it cause the thrombocytopenia that is associated with infusion of PAF in other species[9]. However, it might stimulate the release of biologically active mediators from platelets which could contribute to the ulcerogenesis. This possibility was studied in rats made thrombocytopenic 24 h previously by i.v. injection of an anti-platelet serum raised in rabbits against rat washed platelets[19]. Reduction of the number of circulating platelets by 85–90% below that of control rats treated with normal rabbit serum did not reduce the damage (mean score 2.2 ± 0.6; $n = 3$) produced by PAF (50 ng per kg per min).

Our studies demonstrate that PAF is a potent ulcerogenic agent in the rat stomach. In a previous study on ischaemic bowel necrosis, haemorrhagic lesions were observed in the rat gastric mucosa after i.v. injections of very high doses of PAF in combination with endotoxin[13]. While the hypotensive actions of PAF could contribute to its ulcerogenic actions, especially at the higher doses, this is unlikely to be the sole mechanism. However, a local vascular action of PAF may well be important. Indeed, the histological observations of vascular congestion suggest that stasis may be a precipitating event in the ulceration process. Stasis could occur as a result of vasoconstriction, exudation of plasma, or through aggregation of one or more of the cellular components of blood. PAF has potent pro-aggregatory and degranulatory effects on neutrophils both *in vivo*[20] and *in vitro*[21]. Infusion of PAF to rabbits leads to substantial neutropenia, perhaps as a result of sequestration of neutrophil aggregates in the lung and other tissues[20,22]. Sequestration of neutrophil aggregates in the stomach, as observed in the histological sections taken after PAF administration, could thus contribute to congestion of the mucosal vasculature. Generation of free radicals and release of lysosomal enzymes following neutrophil aggregation could also contribute to the tissue damage induced by PAF.

Gastric damage was observed with a dose of PAF as low as 20 pmol per kg per min, the total dose administered over 20 min being 400 pmol per kg. Concentrations of PAF of 4.7 nM have been found in the blood of rats during endotoxin shock; this concentration could be achieved by an infusion of PAF at 300 pmol per kg[12]. Hence, the doses of PAF which produced extensive gastric damage in the present model are within the range of concentrations found *in vivo* in a model of a disease associated with acute gastric ulceration. The use of specific PAF antagonists will help to clarify the contribution of endogeno PAF to such gastric damage. Whether the release of PAF fr circulating or entrapped blood cells under other circumstanc such as after haemorrhagic shock, also contributes to gast damage is not yet clear. It is conceivable that in conditio characterized by infiltration of inflammatory cells, or in sequence of events following local tissue damage, PAF may released directly into the mucosa. Thus, both systemic and lo release of PAF could initiate or further amplify gastric ulcerati under pathological conditions.

Systemic administration of 1-methyl-4-phenyl-1,2,3,6-tetrahyd pyridine (MPTP) is neurotoxic to cerebral dopaminergic neuro in several animal species, and can cause parkinsonism in man[1] The mechanism of this action may be indirect. MPTP is oxidi in the brain to a pyridinium species, 1-methyl-4-phenylpyrid (MPP^+)[6]. This oxidation is greatly decreased by inhibition monoamine oxidase B[6], as are the biochemical effects of MP in the mouse[7] and its neurotoxicity in the monkey[8]. We now s that MPP^+ exerts a powerful neurotoxic action on the nigrostria dopamine system of the rodent.

The neurotoxic potential of MPP^+ in the mouse was initia investigated by injecting MPP^+ (10 μg) dissolved in distil water into the ventricular system, a route selected to avoid difficulties of penetrating the blood–brain barrier. Mice recei one injection daily for 3 days, via chronically in-dwelling gu

Table 1 Neurotoxic action of MPP^+ and MPTP infused into rat substantia nigra revealed as depletions of dopamine/metabolites in posterior striatum

Treatment	Dopamine (ng per mg tissue)	DOPAC	HVA (pg per mg tissue)	Serotonin	5-HIAA
Vehicle	2.70 ± 0.4	242 ± 23	166 ± 36	338 ± 62	281 ± 24
MPTP	2.44 ± 0.2	281 ± 17	144 ± 78	485 ± 41	307 ± 22
MPP^+	0.74 ± 0.1*	87 ± 9*	44 ± 8†	414 ± 44	274 ± 15

Male Sprague-Dawley rats (300-325 g) were implanted with chronically in-dwelling guide cannulae aimed at the substantia nigra zona compacta (Ant.2.2, Vert.1.8, Lat. ± 2.0)[11,12] and were subsequently implanted subcutaneously (in the interscapular region) with two Alzet osmotic minipumps. MPTP (Research Biochemicals Inc.) or MPP^+ dissolved in distilled water was continuously infused bilaterally via injection units connected to the pumps at a rate of 0.48 μl h^{-1}, containing 10 μg per day, for 4 days. Levels of dopamine, serotonin and their metabolites in the posterior striatum were determined by high-pressure liquid chromatography. Values are expressed as the mean ±1 s.e.m.; $n = 5$.

* $P < 0.01$ and † $P < 0.05$ compared with vehicle treatment; Mann-Whitney *U*-test.

cannulae, and were killed on day 4. At this time, striatal dopamine levels were reduced by 35%, and 3,4-dihydroxyphenylacetic acid (DOPAC) levels by 27%, with no reductions in levels of homovanillic acid (HVA), serotonin or 5-hydroxyindoleacetic acid (5-HIAA). Thus, MPP^+ was shown to have actions on dopaminergic neurones, the modest reductions perhaps reflecting the difficulties encountered by MPP^+ in penetrating the neostriatal complex from the ventricular system.

Consequently, in a second series of experiments, MPTP and MPP^+ were infused directly into the dopaminergic cell body group in the substantia nigra of the rat. The rat was a particularly suitable species for these studies because it is relatively insensitive to the neurotoxic actions of MPTP[6,9]. To minimize problems of nonspecific damage, MPTP and MPP^+ (10 μg per 24 h) were infused bilaterally into the substantia nigra via chronically in-dwelling guides and injection units. Motor functions, including locomotor response, ability to climb and grip on a vertical wire grid, and the presence of rigidity in the limbs and trunk were recorded daily during 4 days of infusion. Rats were killed 1 day and 1 month after the infusions and the striatum was dissected for analysis of the content of dopamine and serotonin, and their metabolites, and for estimates of ^{3}H-dopamine uptake into striatal synaptosomes.

Even when MPTP was infused continuously into the substantia nigra, there was no loss of striatal dopamine or its metabolites (Table 1). There was a small decrease in ^{3}H-dopamine uptake into striatal synaptosomes 1 day after cessation of MPTP administration (vehicle, 0.91 ± 0.01; MPTP, 0.62 ± 0.15 pmol ^{3}H-dopamine per mg protein per 6 min, $P < 0.05$, $n = 4$), but this was not present 1 month after MPTP treatment (vehicle, 1.05 ± 0.17; MPTP, 0.82 ± 0.08 pmol ^{3}H-dopamine per mg protein per 6 min, $P > 0.05$, $n = 4$).

In contrast, MPP^+ infused into the rat substantia nigra was markedly neurotoxic to dopamine function; striatal dopamine levels 1 day after the infusion were reduced by 73%, DOPAC levels by 64% and HVA by 27%, with no change in levels of serotonin or 5-HIAA (Table 1). Infusion of MPP^+ caused a large decrease in ^{3}H-dopamine uptake at both 1 day and 1 month post-infusion (1 day, 0.27 ± 0.04; 1 month, 0.36 ± 0.04 pmol ^{3}H-dopamine per mg protein, both $P < 0.001$ compared with vehicle controls (results above), $n = 4$).

MPP^+ infused into the substantia nigra caused profound motor deficits, in contrast to the less severe effects of MPTP. Both neurotoxins caused reductions in locomotion and loss of ability to coordinate movements of the front limbs, seen as an inability to grip on a vertical wire grid and so climb on the grid. However, the effects of MPP^+ were more severe, with additional loss of the ability to use the hindlimbs to grip and climb on the vertical grid, and the development of rigidity in forelimbs, hindlimbs and trunk (Table 2). These effects developed within 12 h of the start of MPP^+ infusion into the substantia nigra and were maximal by day 2. The overall impression of the effects of MPP^+ treatment was the appearance of a severe motor impairment.

Table 2 Motor impairment caused by the bilateral infusion of MPTP and MPP^+ into rat substantia nigra

Treatment	Locomotor activity	Grid test	Rigidity
Vehicle	92 ± 10.0	20 ± 0.0	0.0 ± 0.0
MPTP	40 ± 5.1*	9.3 ± 0.8*	0.0 ± 0.0
MPP^+	13 ± 1.4*	0.0 ± 0.0*	15.0 ± 0.0*

Locomotor activity was measured daily in individual photocell cages; interruptions of beams were recorded every 5 min and summed to give counts per 60 min. Locomotor depression was maximal by day 2; data are given for day 3 (±1 s.e.m.). Deficits in limb movement were assessed using a vertical wire grid and scored as follows: (1) climbing upwards or sideways on grid; (2) maintaining position on grid for 30 s; (3) gripping grid with forepaws; (4) gripping grid with hind paws. Results are expressed as the total score (±1 s.e.m.) for five test sessions on days 2-4 of infusion. Rigidity was noted as being present or absent in the forelimbs, the hindlimbs and the trunk, giving a maximum score of 3 for each animal. Results are expressed as the total score (±1 s.e.m.) determined during five test sessions on days 2-4 of infusion. $n = 5$.

* $P < 0.001$ compared with vehicle treatment; one-way ANOVA followed by Dunnett's test.

These studies in the rodent emphasize that the oxidative metabolism of MPTP is required for expression of its neurotoxic action, and that one metabolite, MPP^+, found in monkey and mouse brain after MPTP administration[6], has powerful neurotoxic action on the nigrostriatal dopaminergic system. The previous uncertainty as to whether MPTP neurotoxicity results from the formation of MPP^+ or from the oxidative processes forming MPP^+ is thus partly resolved; MPP^+ itself appears neurotoxic, although histological assessment of the extent and specificity of the neuronal damage caused by MPP^+ is required. It remains possible that the oxidative processes forming MPP^+ also have neurotoxic potential. However, the nature of the motor deficits and severity of the loss of striatal dopaminergic function caused by MPP^+ may provide clues to the pathogenesis of Parkinson's disease.

This work was supported by the MRC, the Parkinson's Disease Society, the Wellcome Trust and the SERC. We thank Dr W. Langston for the gift of MPP^+.

A large anion-selective channel has seven conductance levels

Mauri E. Krouse, Gavan T. Schneider & Peter W. Gage

Department of Physiology, John Curtin School of Medical Research, Australian National University, ACT 2601, Australia

Ion channels have generally been found to have two predominant conductance levels thought to be associated with 'open' and 'closed' states, but intermediate (subconductance) states have also been reported[1-3]. We have now found that a large conductance, anion-selective channel in pulmonary alveolar epithelial cells[4] can adopt any of six open levels of conductance that are integer multiples of 60–70 pS. The channel is usually either fully open or fully closed. The frequencies of the different conductance levels are inconsistent with the notion that there are six independent channels. We suggest that the channel consists of six conducting pathways in parallel, 'co-channels', with a shared gating mechanism that can synchronously render all of them non-conducting. Other channels with lower maximum conductance may operate in a similar way but multiple conductance levels would not easily be detected because of a less favourable signal-to-noise ratio.

Currents were recorded at room temperature (21-25 °C) from inside-out patches excised from the apical surface of cultured mouse alveolar type II cells. Recording procedures are described elsewhere[4]. Excised patches were held at 0 mV and then stepped to positive or negative potentials to record currents. Following a step in potential, patches are seen to contain from 0 to 4 channels, each with a conductance of ~400 pS. In most patches, channels become inactivated with time, becoming completely inactivated within 6 s to 10 min and inactivating more rapidly the further the potential is stepped away from 0 mV. Inactivation could be reversed by returning to 0 mV. Thus, the large conductance anion channel in pulmonary epithelial cells has characteristics in common with large conductance anion channels described in other tissues[5-7].

Selected current records, obtained from an excised patch in which there appears to be only one 400-pS channel following a voltage step from 0 to 57 mV, are shown in Fig. 1. This channel displays rapid inactivation so that no full openings are observed after 10 s. The records shown in Fig. 1 were chosen to illustrate the different current levels and types of channel behaviour. In Fig. 1*A*, the channel is open most of the time, closing several times near the middle of the record. The mean current through the open channel (upper level) is 23 pA, corresponding to a conductance of 404 pS (holding potential 57 mV, null potential 0 mV), similar to previous reports[4] of the conductance for this channel. The noise level (flickering) is greater when the channel is open than when it is closed. This phenomenon is even more noticeable in Fig. 1*B*, *C*; *B* shows the current fluctuating between 21 and 15 pA, the latter being about two-thirds of the open current, whereas *C* shows the current fluctuating between 23 and 12 pA, the lower level being about half the maximum current. Occasionally, the current fluctuates between 0 and 7.5 pA (Fig. 1*D*) and, less frequently, clear steps occur from the closed state to the lowest level, which is about one-sixth of the maximum current (Fig. 1*E*). In all 41 patches studied, only transitions between the fully open and closed states are seen at first, followed by the invariable appearance of subconductance levels.

Records such as those shown in Fig. 1*A*–*E* strongly suggest that there are several subconductance states of these channels. Clearer examples of the six current levels recorded in several different patches are shown in Fig. 1*F*. The levels are always approximately an integer multiple (up to six) of one-sixth of the maximum current, although it is often difficult to differentiate between the maximum and five-sixth maximum levels because of rapid transitions between the two. Furthermore, the average current at the lowest level is often less than one-sixth

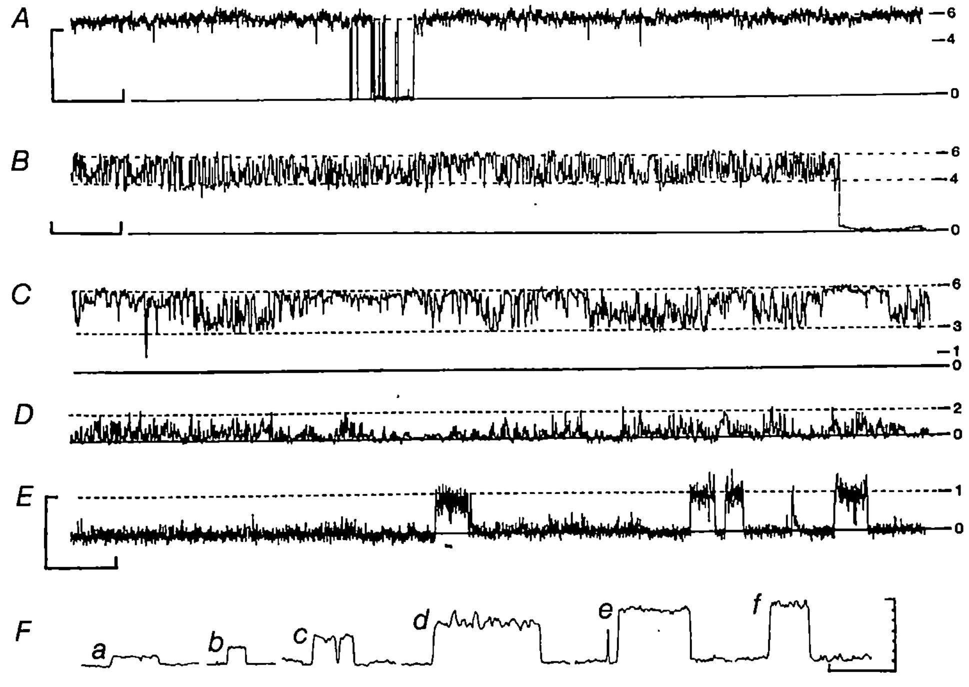

Fig. 1 *A*–*E*, Records of currents from an excised, inside-out patch of membrane following a voltage step from 0 to +57 mV (voltage of the bath solution on the cytoplasmic surface of the membrane with respect to the pipette solution). The bath and pipette contained the same solution (140 mM NaCl, 3 mM CsCl, 1 mM $MgCl_2$, 2 mM $CaCl_2$, 10 mM glucose, 10 mM Na^+-HEPES, *p*H 7.3). Upward deflections represent positive current flowing from the bath into the pipette (chloride ions moving in the opposite direction). Current was recorded on an FM tape recorder and subsequently played back through a 4-pole Bessel filter (−3 dB at 5.3 kHz), digitized at 25 μs per point and analysed by computer. Records were selected to show different current levels. Numbers on the right of each record and the broken lines show integer multiples of the lowest level seen (*E*); solid lines show the baseline (closed channel) current level. *A*, Transitions between fully open and closed levels (the commonest transitions). *B*, Transitions between the fully open and fourth levels (followed by a transition to the closed level) with the fifth level also present. *C*, Transitions between the fully open and third levels with the fourth and fifth levels also present. *D*, Transitions between the closed and second level with the first level also present. *E*, Transitions between the closed and first level. The dotted line was drawn at one-sixth of the maximum current level. Scale bars: *A*, 20 pA and 100 ms; *B*–*D*, 20 pA and 20 ms; *E*, 7 pA and 500 ms. *F*, Records obtained from five different patches clearly showing maintained current levels at 1, 2, 3, 4, 5 and 6 (*a*–*f*) times the first (lowest) current level (*a*). The Bessel filter cutoff (−3 dB) was set in the range 0.7–3.3 kHz.

of the maximum level (see Fig. 1*E*), presumably because of rapid flickering between open and closed states[10].

Amplitude histograms of currents recorded from individual patches also provide evidence for multiple conductance levels. Figure 2 shows an amplitude histogram of a 91-s record from the same patch as in Fig. 1. The period was chosen because it contained several lowest-level openings, including those in Fig. 1*E*. The histogram has peaks showing that there is a significant probability that the current could be at several levels between the fully open and closed levels. The units in the lower abscissa are one-sixth of the current between the first and last peaks. The second peak at ~5 pA gives a first-level current less than one-sixth of the maximum current level, as expected if there is rapid flickering between the first level and the closed state.

One simple model for the multiple current levels is that they are caused by contributions from six channels opening and closing independently. However, two characteristics of the currents exclude this possibility. First, following a shift in potential, some patches have conductances that are integer multiples of 400 pS and the conductance decreases in 400-pS steps. It would be a remarkable coincidence if all the 41 patches studied here contain an integer multiple of six independent channels and if the channels then dropped out in groups of six. Second, more than half of 1,000 measured transitions between clearly distinguishable levels appear to be (within less than 100 μs) between the fully open and closed states, with no sign of an intermediate level even at 4 kHz bandwidth. If a single channel has a mean open time of 3 ms (approximately the mean duration of the first conductance level; see Table 1), the probability of six channels closing within a 100-μs period would be $(1-\exp(-100/3{,}000))^6$, that is, less than 10^{-8}. It seems very unlikely, therefore, that independent channels with a conductance of ~70 pS could produce the patterns of current levels we have observed.

Several other models to explain our observations proved unsatisfactory. For example, there could be six sequential open conformations of a single channel, each with a different conductance. This model requires the unlikely assumption that the difference in conductance is the same between each state. Moreover, we were unable to find a set of rate constants linking such states which would give rapid transitions between the closed and fully open states and still allow persistent intermediate states such as those observed. Alternatively, there could be six open states of a channel connected via a single closed state but this would suggest that different current levels should be separated by a closed level, which was seldom seen.

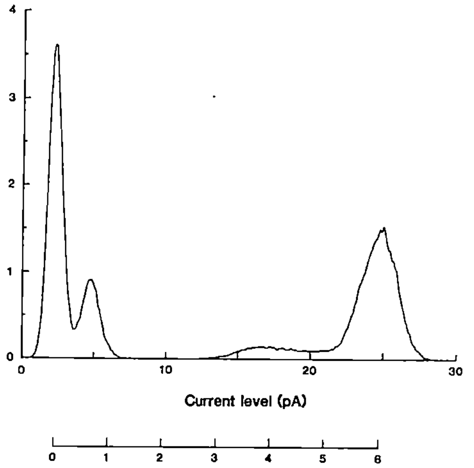

Fig. 2 Current amplitude during a 91-s recording period from the same patch as in Fig. 1*A–E*. The section of record was chosen for analysis because it contained examples of the first (lowest) current level and, for this reason, the histogram shows a peak at ~5 pA. Generally, only three peaks are seen (0, 4, 6), the peak for the lowest current being spread out and covering the 0, 1 and 2 current levels. The lower abscissa has units that are one-sixth of the difference between the peaks of the lowest and highest current amplitude. The probability of residing in each of the levels is given by the area under each of the peaks. The offset of the first peak from zero indicates a seal resistance of ~25 GΩ.

The appearance of seven equally spaced conductance levels together with step changes between the closed and fully open states suggests that the channel consists of six identical conducting units (co-channels) that function cooperatively to form a single channel. We believe that our results can be explained by a model in which the channel consists of a cluster of six co-channels sharing a common regulatory 'gate' that can occlude all six simultaneously. A similar model with two conducting units has been proposed previously by Miller to explain the behaviour of a small chloride channel in electroplaques[8]. It has also been suggested that the selectivity of high-conductance potassium channels arises in a similar way[9].

To test this model, we analysed currents from two patches that exhibited fully open states at the end of recording periods of 30–100 s. Measurements were made of the time spent at each of the seven levels (0, 1, 2, 3, 4, 5 and 6 times one-sixth of maximum). To exclude noisy transitions between levels, we only accepted those levels maintained for ⩾0.3 ms. Because of the

Measurements of current levels lasting longer than 0.3 ms in recordings of current from two patches in which the channel continued to show full openings at the end of a recording period. Because of difficulty in distinguishing the fifth and sixth levels, the two are taken together. Observed occupancy gives the fraction of the total measurement time that a channel was at a given current level, including closed. The fraction of the total measurement time that co-channels were open (excluding the closed times that were considered to be due, primarily, to the presence of a regulatory gate) is given by open-state occupancy. Predictions of the occupancy of any of the current levels are given in the sixth column. To calculate the probabilities, it was assumed that there were six identical, independent co-channels, each with a p of 0.71. The predicted occupancies were calculated from the binomial equation $P_k=\binom{6}{k}p^k(1-p)^{6-k}$ (that is, $P_0=(1-p)^6$, $P_1=6p(1-p)^5 \ldots P_{5+6}=6p^5(1-p)+p^6$). Deviations between predicted and observed occupancies at the lower levels are not surprising because: (1) the smaller number of events increases the measurement error; and (2) the exclusion of rapid flickering from the data would affect measured mean open time. The predicted open times were obtained from the assumption of a simple two-state model, a co-channel open probability of 0.71 and the observed open time of the 5+6 level (see text).

continuous flickering between the five-sixth and six-sixth level, the two were difficult to distinguish so were taken together and treated as a single level. The frequency of the closed state is an underestimate because we included only those times between two clearly identified open states: we excluded closed states showing rapid flickering. We have not included long closed periods (often of several seconds duration) which occur between bursts of channel openings. Results of our analysis are shown in Table 1. The fraction of the total time for which a current level was observed is given in column 4 (observed occupancy). The open-state occupancies, obtained by excluding the closed state (0 level), are also shown in Table 1.

If we assume that we are observing current flowing through six co-channels opening and closing independently (except when the channel is closed by a shared gate), the open-state occupancies should conform with a binomial distribution. Occupancies predicted for six co-channels, each with an open probability (p) of 0.71, are given in Table 1. There is good agreement between the observed and predicted open-state occupancies. Again, the discrepancy between the observed and predicted 0-level occupancies highlights the need to propose a superimposed shared gating mechanism that occludes all six co-channels at least 14.5% of the time.

Such a binomial scheme can be used to predict the probability of transitions between current levels[8]. If the behaviour of each co-channel can be described by

$$\mathrm{C} \underset{b}{\overset{a}{\rightleftharpoons}} \mathrm{O}$$

where C and O are the closed and open states of each co-channel, a is the opening rate and b the closing rate, it is possible to predict open times of multiple co-channel states. For example, the rate of leaving the state associated with four open co-channels is $4b+2a$, where $4b$ is the rate for one of four open co-channels closing and $2a$ the rate for one of two closed co-channels opening. If the probability of each co-channel being open is 0.71, as before, then $a/b=p/1-p=2.45$ and the rate of a channel leaving the four-co-channel state is $8.9b$. Rates of leaving each of the other multiple-co-channel states can be calculated in a similar way. The predicted open times (reciprocals of the rates) of each multiple-co-channel state were calculated from a value of b obtained from the mean duration of the $5+6$ level (for which most data were available, see Table 1). There is clearly good agreement between observed open and predicted open times (Table 1).

Thus, evidence for our co-channel model is: (1) channels of high conductance that show seven equally spaced conductance levels; (2) a high percentage of rapid transitions between closed and fully open states; (3) open-state probabilities and open times consistent with the existence of six identical, independent co-channels; and (4) a closed-state probability and closed time greater than expected from six independent co-channels.

This kind of channel behaviour is probably not confined to pulmonary alveolar cells. Records of currents from high-conductance chloride channels in a variety of tissues[5-7] show subconductance states and transitions similar to those described here. Furthermore, multiple conductance levels between fully open and closed levels have been noted in other large-conductance channels[11-13] and single subconductance states have been seen in smaller channels[1-3]. Indeed, it has been reported recently that a potassium channel in an *Aplysia* neurone[14] displays both equally spaced conductance levels and rapid transitions between fully open and closed states. Such observations raise the possibility that a mechanism involving clusters of co-channels with a shared gate functions in a wide variety of channels in other preparations. If so, the phenomenon is important in channel assembly and function and must be taken into account during analysis of single-channel currents and in the formulation of theories of ion permeation through membranes.

After submission of this paper, a high-conductance chloride channel with 17 conductance levels in a molluscan neurone has been reported[15] and we have observed channels with more than seven current levels.

We thank John Dempster for allowing us to use some of his analysis programs, Mark Rogers for help with analysis and Dr Alasdair Gibb for helpful comments on the manuscript.

Permanent distortion of positional system of *Xenopus* embryo by brief early perturbation in gravity

Jonathan Cooke

Laboratory of Embryogenesis, National Institute for Medical Research, The Ridgeway, Mill Hill, London NW7 1AA, UK

The formation of a body plan from an initially radially symmetrical egg during animal development is presumed to involve a 'positional system'[1,2] and a subsequent mechanism of local response to position values provided by this system. Early gene products intimately connected with the latter response mechanism have been identified in *Drosophila*[3-5], and because these share conserved sequences with possible counterparts in vertebrates, there is renewed interest in understanding the physiological nature of the positional system itself in a vertebrate embryo. In the frog *Xenopus*, body position value appears to be specified in outline across much of the egg material by stages comprising a few cells, after only ~2 h of development[6-10]. This is already suggestive of a structural or mechanical recording system rather than a diffusion-controlled gradient. I describe here an experiment aimed at perturbing the positional system by causing gravity-driven rearrangements within eggs which conflict with their own, self-organizing rearrangements near the time of first cleavage. The system appears to retain its full regulatory properties during only a brief time interval, so that records of positional profiles disturbed at the close of that interval are permanent, and give rise to systematically abnormal body patterns in otherwise healthy larvae. The results are inconsistent with the notion that *Xenopus* primary pattern results from a set of determinant 'plasms' in the egg, or from a mechanism dominated by long-range diffusion of molecules[11,12].

The direct action of the positional system occurs mainly in the yolky, endodermal part of the egg. Coordinated mesodermal and ectodermal body contributions are set up later by appropriately balanced spatial patterns of inductive activity emanating from the endoderm[13-16]. The deviant bodies that I shall describe here are detectable on external form alone (top row, Fig. 1), but I have also analysed the mesoderm, whose anatomy is sufficiently differentiated at early larval stages. After 48 h of development (stage 29-30; ref. 17), all mesoderm cells can be scored histologically as members of the different axial pattern elements (see Fig. 2), but there has been little growth to obscure the proportions in which the tissue was originally partitioned

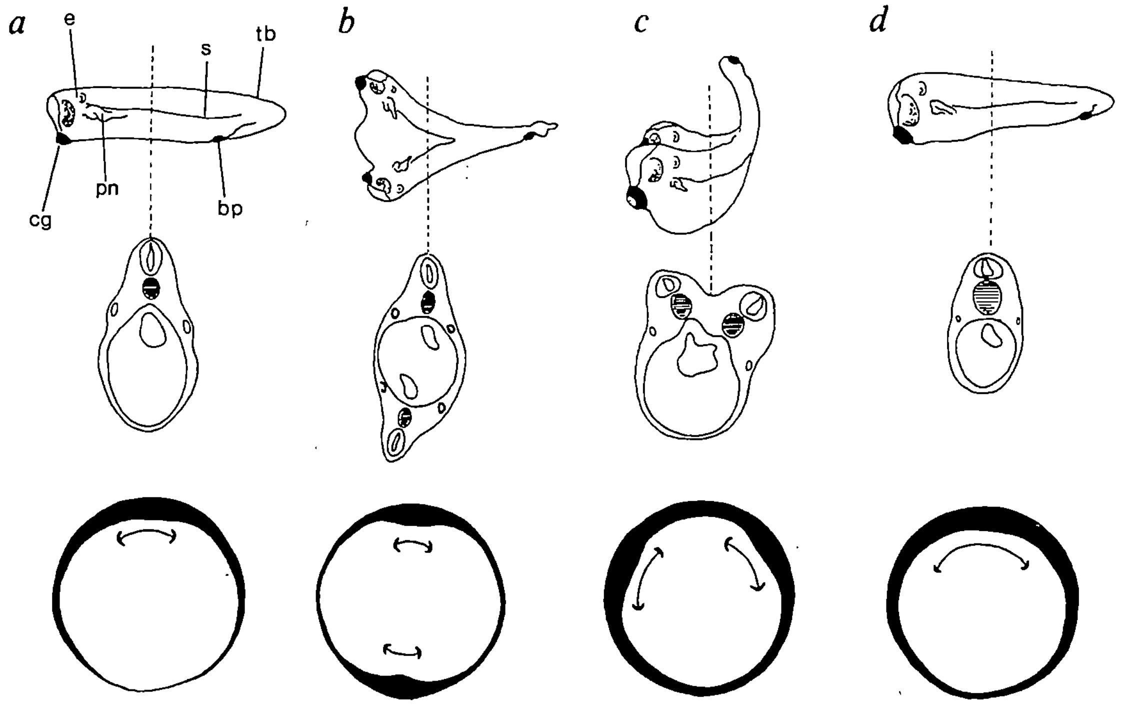

Fig. 1 Twinned and imbalanced body patterns seen after tilting eggs in gravity, and a suggested interpretation. The top row shows camera lucida sketches of the normal body form (*a*) and of three typical experimentally produced body forms (*b*–*d*) at the larval stage used for pattern analysis. *b*, A twinned pattern with approximately equal and opposite partial axes and moderate deficiency of posterior pattern. *c*, A twinned pattern with adjacent and massively constructed partial axes but an extreme deficiency of posterior pattern. *d*, An imbalanced single pattern with systematic over-allocation to dorsal and anterior structure at the expense of posterior structure. The second row shows schematic transverse sections of each body form, at approximately 8th somite level. Neural tubes, notochords (shaded) and the yolky gut mass with a single or double archenteric cavity are shown. Note the relative sizes of the notochord in cross-section. The third row shows corresponding egg outlines in the horizontal plane relative to normal gravity orientation. The thickness of the outline represents the profile around the egg yielding each body form, with respect to levels of activation, or 'body position values', recorded by the early-acting positional system. With the normal, complete profile (*a*), the mes-endodermal body plan is built essentially from head plus notochord towards tail, around the egg meridians from top to bottom of the outline, the position of sperm entry being near the bottom. The separate internal arc opposite the thickest part of the outline represents arbitrarily the normal extent of an egg sector specified for allocation to notochord production. The outlines of *b* and *c* suggest how, when two such peaks of activation arise in one egg after early perturbation of the plasm shifts, interactive effects due to their relative positioning may influence greatly the profile attained by each, and hence the relative amount of the system allocated to notochord and anterior structure. There is a corresponding variable sacrifice of the posterior pattern complement. Such variation is observed (see text). Outline *d*, corresponding to a single but incorrectly proportioned axial pattern, is perhaps an extreme version of type *c* with partial regulation fusing the original centres of activation. Externally visible larval features: e, eyecup; cg, cement gland; pn, pronephros; s, line of lateral edges of somites; bp, proctodaeum (original blastopore); tb, tailbud.

into founder territories for these structures[18]. Mesodermal pattern balance in individuals is therefore assayed by scoring the nuclei encountered on every fifth 7-μm section of the transverse series, and sampling $\sim 10^4$ cells (or one-third of the total when nuclear size and section thickness are properly considered[19]).

The mesodermal pattern is highly consistent among individual normal embryos, and is subtle in the sense that characteristic proportions of the totals of somite and lateral plate cells are allocated to these structures at each level in the axis[9]. This feature, a measure of the relative 'head-' or 'tail-heaviness' of tissue distribution along the normal series of somite segments, can be quantified as the 'somite index' (see Table 1), which has a certain range of normal variation.

My attempt to force the system outside its normally regulated performance was based on recently published work concerning mechanical aspects of the pre-cleavage events[6,7,20–22]. After fertilization, a system of spontaneous sliding displacements between deep egg regions and the surface structure, driven in relation to the position at which the sperm aster is developing, normally orientates and activates the development of the body from the egg's substance. Any artificially maintained tilt of the eggs away from their natural orientation in gravity, at times when their self-generated movements are occurring, can override the orientating effect of the sperm. Normal patterns then develop, but are symmetrical around that plane in which gravity has caused the egg contents to rearrange. There is much to suggest[10,23] that the total set of movements within the normal egg, more than merely orientating its pattern formation, is quantitatively related to normal completeness and proportioning of the pattern itself.

Towards the end of the pre-cleavage interval, progressive 'gelling' of some egg component appears to record unalterably the net results of all preceding reorganizations in setting up a pattern, whether these were dominated by the natural mechanism or by artificial tilt. Therefore, tilting in gravity at a late stage in this sensitive period, in directions calculated to conflict widely with the system of activation orientated by sperm entry in each egg, might lead to the recording of positional profiles different from those resulting from either natural or imposed systems when acting alone. Such a regime tilt through 70–100° in planes that raised the sperm entry point (s.e.p.) very high in gravity, beginning at 65–85% of the time from fertilization to first cleavage, was accordingly applied to experimental populations of eggs from synchronously fertilized clutches. At the chosen temperature (19 °C), this involved tilting at between 65 and 85 min after fertilization. The eggs were released to orientate freely in gravity at the 8-cell stage after 1 h. Control eggs were subjected to identical conditions except that they were not tilted (for production and handling of eggs in such experiments, see refs 8, 20, 21).

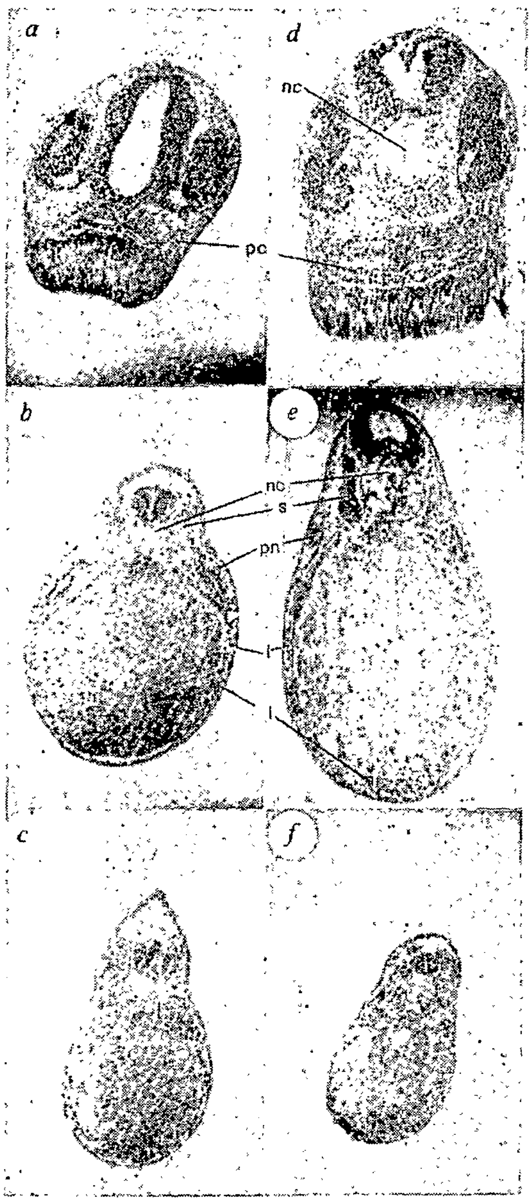

Fig. 2 Internal structure of normal and pattern-imbalance imbalanced larvae. *a–c*, Sections taken at different levels in control larva at stage 29; *d–f*, equivalent sections in a sibling morphologically 'disturbed' after pre-cleavage tilt. *a*, *d*, Level of forebrain, eyecups, ventral prechordal mesoderm and cement gland. Note the massive size of the latter two regions in the disturbed case, and the intrusion of the massive notochord cross-section into this anterior level. *b*, *e*, Level of highest cell count in pronephros (approximately opposite somite 5). Note the greater cross-sectional area of the gut mass, under-allocation to pronephros, the massive notochord and wide floor plate of the neural tube, and the large lateral plate population in the disturbed case. *c*, *f*, Level just anterior to the proctodaeum (blastopore). Note the small cross-section and diminished scale of construction of the entire mesoderm in the disturbed case. Only at this level does the cell number in the notochord cross-section return to normal values. nc, Notochord; pc, prechordal mesoderm; pn, pronephros; l, lateral plate; s, somite.

Six populations of ~80 eggs each were subjected to the experimental regime, with tilting of each individual in sequence being completed across the 20-min period. Synchronously fertilized siblings in similar numbers were used as controls for each population. After 2 days, five of the experimental populations included instances of twinned or mirror-duplicated pattern and of a characteristic, 'imbalanced' single body pattern, in normally healthy larvae. The single-body pattern involved large ventral
head and anterior trunk regions but small, slender poste
parts (Fig. 1*d*). There were between 2 and 6 twins per populat
(26 in total), in contrast to only one among the 450 contr
Affected populations showed between 4 and 12 imbalan
single bodies (39 in all), whereas none was seen either am
the controls, in three populations where s.e.p. up tilt was impo
before the midpoint of pre-cleavage, or in three populati
where this tilt was applied for 1 h between the 4- and 32-
stages.

Larvae showing the externally deviant morphology all
quite abnormal balances of mesoderm pattern in relation t
the controls, or to apparently normal members of their exp
mental batches. This is illustrated for two typical sets of s
bodies in Table 1. That the control/experimental differe
shown in Figs 1*a*, *d* (camera lucida) and 2*a–f* (transv
section) may appear undramatic to the non-specialist, i
measure of the precision of performance of the normal pat
formation under study. As in previous work of this kin
Xenopus, an abnormal pattern *per se* is not associated
abnormal numbers of mesoderm cells[18]. Internal features of
syndrome (for 20 abnormal mesoderms analysed complet
are as follows: (1) The cellular allocation to notochord is 1.5
times normal, the excess being concentrated towards the ante
of the axis. (2) The allocation to the ventral pre-chordal st
ture, and particularly the anterior lateral plate, is enhan
while that to the total somite is usually somewhat reduced.
pre-chordal imbalance is reflected in the deep, broad head
excessive area of cement gland induced in the head ectode
(3) Although the total somite segment number is correct,
axis is anterior-heavy. While the slender anterior somites
allocated at least their normal cell numbers, the cross-secti
of those in the trunk and tail are progressively reduced be
the norm (Fig. 2*b*, *c*, *e*, *f*; see also Table 1). The posterior lat
plate and tailbud tissues are also under-represented in rela
to the massive 'chest' tissue. (4) The allocation to the proneph
is frequently abnormally small, down to less than half the nor
6–9% of mesoderm (Fig. 2*b*, *e*), or is even absent.

The twinned bodies turn out to represent opposed pairs
partial body patterns, the regions represented in each axis be
the entire notochord and those other parts of the plan that
over-represented in the imbalanced singles. The pronephros
those parts of the somite pattern normally contributed from n
the s.e.p. meridians, are reduced or absent. Two features of
variation seen among these twin patterns are particularly in
mative concerning the dynamical properties of the early p
tional systems. The first concerns notochord allocation. In m
cases the two notochords lie relatively close together, suggest
that the centres of 'activation' of two positional systems aris
in the egg were situated considerably less than 180° apart. Th
is then normal or supranormal cellular allocation to e
notochord, and thus twice or more the normal allocation to
structure (Fig. 1*c*, second and third rows). In other cases, wh
the midlines of the twinned system are equal and opposed
the egg, there is a diminished allocation to each notochord s
that the total allocation is little above normal (Fig. 1*b*).
second noteworthy feature (not represented in Fig. 1) is t
one or both patterns may be locally incomplete at the extremi
of the head and anterior notochord, and there may be a la
asymmetry in partitioning of the total cell population to sma
and larger, complete or anteriorly incomplete patterns.

Figure 1 (third line) offers an interpretation of the patte
in terms of profiles with respect to some variable that could
termed position value for pattern contribution, encoded into
structure around the egg margin. All the imbalances produ
are systematic over-allocations of egg meridians to those posit
values which are normally specified relatively far from the p
of sperm entry, and are associated with the fastest develop
meridians of the egg and gastrula.

It is clear that abnormal profiles of the primary positio
variable, recorded at an essentially pre-cellularized stage,

be maintained for many hours and cell cycles; they are ultimately transmitted from endodermal regions as aberrations in the balance of mesoderm specification. Positional systems that are incomplete in the opposite sense—that is, lacking dorso-anterior values entirely—show similar stability from egg to larva[6,22,23]. Such behaviour, and the rapidity with which the system is set up, is very different from what would be expected from a reaction/diffusion or source/diffusion morphogen landscape, with substance concentration being registered as the position value[11,12]. The various stably maintained asymmetries that are seen in twinned positional profiles also deviate from the behaviour expected of reaction/diffusion. On the other hand, the fact that simple mechanical manipulation can alter drastically the relative allocations to different parts of the pattern in the egg as a whole, is scarcely compatible with the idea that a set of determinant plasmas is simply deployed by the pre-cleavage events.

Table 1 Pattern balance in sibling sets after exposure of eggs to an experimental regime of gravity re-orientation

	3	8.5	37.7	5.0	48.8	2.0
	4	9.6	32.7	6.2	51.5	2.0

Somite ratio is the mean maximum number of nuclei seen in transverse sections through somites 14-16 inclusive, divided by the equivalent value for sections of somites 4-6 inclusive. This ratio is indicative of the way in which mesoderm has been allocated to form the pattern of different axial levels, and values between 2.0 and 3.5 characterize the normal embryos from various ovulations. S, somite; PN, pronephros; NC, notochord; LPL, lateral plate.

Mechanochemical models of pattern production (see, for example, ref. 24), invoking the generation of local variations in some non-fluid aspect of the egg's structure that are then inherited by the blastomeres, may have relevance to this relatively small yet rapidly developing vertebrate egg. A long-term research goal must be the elucidation of ways in which structural or physiological modulation of early cellular material can stably affect the local developmental rate[6,7,23] and, ultimately, set position-specific modes of transcription in nuclei. Possible reasons for the previous report of prolonged regulatory ability for body pattern formation, following other operations carried out on *Xenopus* blastula stages[25], have been discussed elsewhere[8].

I thank Wendy Hatton for histology, and John Gerhart and George Oster for fruitful discussions.

Leprosy is a chronic infectious disease caused by *Mycobacterium leprae*. As with other intracellular parasites, protective immunity is dependent on T cells and cell-mediated immunity[1]. In animal models, immunization with killed armadillo-derived *M. leprae* elicits strong T-cell responses, delayed-type hypersensitivity and protection against viable challenge[2-5]. We have recently shown that killed *M. leprae* can induce delayed-type hypersensitivity in healthy human volunteers[6]. Identification of the *M. leprae* antigens that are recognized by T cells and may be involved in protection has been hampered by the inability to cultivate the organism *in vitro* and by difficulties in antigen purification from limited quantities of armadillo-derived bacillus. Because genes for the major protein antigens of *M. leprae* as seen by mouse monoclonal antibodies have been isolated[7,8], it has become possible to test whether these individual antigens are recognized by T cells. We screened crude λ gtll phage lysates of *Escherichia coli* containing individual *M. leprae* antigens using *M. leprae*-specific T-cell clones isolated from *M. leprae*-vaccinated volunteers. Using this method, we find that nearly half of the *M. leprae*-specific T-cell clones are stimulated to proliferate by lysates containing an epitope of a *M. leprae* protein of relative molecular mass 18,000 (18K).

Healthy human volunteers vaccinated with killed *M. leprae* were sensitized to soluble *M. leprae* antigens[6]. Forty-two T-cell

Peripheral blood mononuclear cells (PBMC) were separated from five healthy volunteers vaccinated with 1.5×10^8 or 4.5×10^8 killed *M. leprae*[6]. 20×10^6 PB (2×10^6 cells ml^{-1}) in complete medium (RPMI 1640+15% human AB serum+1% penicillin/streptomycin) were cultured with 10 $\mu g\,ml^{-1}$ soluble *M. leprae* anti (Batch CD45 from R. J. W. Rees through WHO/IMMLEP Bank) in 25-cm^2 flasks (Costar). Flasks were incubated at 37 °C in an atmosphere of 5% CO_2 and 95% On day 6, cells were washed and recultured with fresh autologous irradiated (2,500 rad) feeder cells+antigen. On day 9, viable cells were recovered on Lympho gradient and cloned in 60-well Microtest plates (Falcon) by limiting dilution[11]. After 7–10 days, cells from growing wells were transferred to 96-well flat-bottom p (Nunc) with fresh autologous feeders+antigen+recombinant interleukin-2 (IL-2; Cetus). After further incubation at 37 °C for 7–10 days, growing cultures were transfe to 24-well plates (Nunc) with 1×10^6 ml^{-1} autologous irradiated PBMC as feeder+10 $\mu g\,ml^{-1}$ soluble antigens of sonicated *M. leprae*+100 U ml^{-1} recombinant Recombinant IL-2 alone was added on day 4. The cycle was repeated every seventh day. When T cells reached 1–2×10^6 ml^{-1}, they were subcultured at 2×10^5 cell well. After 4–8 weeks of cloning, sufficient cells were available for antigen testing. To test antigen reactivity of the clones in a proliferative assay, adherent cells 10^5 irradiated PBMC were distributed into each well of 96-well flat-bottom trays and used as antigen-presenting cells; 10^4 cloned T cells and antigens at opt concentration were added. Antigens were either whole bacilli or soluble sonicates of mycobacteria[12]. Cells were incubated for 48–72 h at 37 °C in 5% CO_2 and air. At 4 h before collection, cultures were pulsed with 0.045 MBq ^3H-thymidine (specific activity 185×10^3 MBq mol^{-1}), incorporated radioactivity was measured[13] median values of counts per minute (c.p.m.) determined. A clone was considered to be proliferating in response to a given antigen when incorporated c.p.m. in cult with antigen minus c.p.m. in cultures without antigen was ≥1,000 and $T/C>2$ (such values in the table are underlined) where T/C = (c.p.m. in cultures with antigen/c. in cultures without antigen). Phenotypes of the T cells (CD4 or CD8) are also listed.

* Soluble *M. leprae* was an ultrasonicated and Millipore membrane (0.22 μm)-filtered preparation of whole bacilli batch CD45 (from R. J. W. Rees).

† SPA 30 was the filtrate of soluble *M. leprae* filtered through Amicon ultramembranes with 30,000 relative molecular moles cut-off (from J. Convit).

clones raised against *M. leprae* soluble extracts were established from five volunteers. These cells were screened for reactivity to antigens prepared from *M. leprae*, BCG, *Mycobacterium tuberculosis*, PPD (purified protein derivative) and other mycobacteria. Eleven of the 42 T-cell clones reacted with *M. leprae* antigens derived from humans or armadillos, but not with BCG or PPD; the responses of these 11 clones to various antigen preparations are shown in Table 1. The response to antigen preparations from other mycobacteria was absent or low, restricted to *Mycobacterium scrofulaceum* (5 clones) and *Mycobacterium nonchromogenicum* (1 clone). The responses of three T-cell clones that exhibit broad mycobacterial cross-reactivity (ATT 2/6E, ATT 4/1F, and ATT 4/4C) are included for comparison.

Five abundant *M. leprae* proteins with relative molecular masses of 65K, 36K, 28K, 18K and 12K have been identified through the use of monoclonal antibodies[7–9]. Each of the genes encoding these proteins has been cloned in *E. coli* Y1089 (ref. 7). Lysogens of λ gtll recombinant phage carrying each of the five *M. leprae* genes were constructed and used to express the antigen of interest in a crude lysate[10]. Similar amounts of *M. leprae* antigen were produced in each of the five lysates. The crude lysates were tested for their ability to stimulate 10 of the *M. leprae*-specific T-cell clones (Table 2); 5 of 10 *M. leprae*-specific T-cell clones responded to *E. coli* lysates containing antigen expressed from the recombinant phage Y3179 (ref. 7). Four of these reactive T-cell clones were established from one volunteer, the other came from a second volunteer. The patt of reactivity of the T-cell clones suggests that the λ gtll ph Y3179 expresses an *M. leprae* epitope that is absent in BC *M. tuberculosis* and other cultivable mycobacteria, but is sha with *M. scrofulaceum*.

The λ gtll clone Y3179 expresses an antigenic determin

Crude *E. coli* lysates containing individual *M. leprae* antigens were prepared by inducing λ gtll recombinant lysogens of the strain Y1089[10]. Single colonies of recombinant lysogens were inoculated into 100 ml of LB medium (*p*H 7.5) and cultures were incubated at 32 °C. When cells had grown to $A_{600} = 0.5$, cultures were transferred to 45 °C and incubated for 20 min. Isopropyl β-D-thiogalactopyranoside (IPTG) was added to 10 mM and the cultures were further incubated at 38 °C for 1 h. All incubations were carried out with good aeration. The cell pellet obtained after centrifugation was resuspended in saline 1/20 of original culture volume and frozen immediately in liquid nitrogen. Thawing of frozen cells resulted in lysis of induced lysogen. To reduce viscosity, crude lysates were briefly sonicated (3 × 10 s) on ice, and then sterilized by Millipore filtration. Lysates were then frozen at −70 °C in aliquots until used. Antigenic activity was lost rapidly on storage at +4 °C, so new vials were used when stimulating T-cell clones. Expression was confirmed by probing crude lysates with the appropriate monoclonal antibodies[7,8]. T-cell clones were tested with different doses of crude lysates as described for other antigens in Table 1. Results are given for 10 μg ml^{-1} of crude lysate and expressed as in Table 1.

* Control cultures without antigen.

Table 3 Proliferation of T-cell clones to Y3179 and other recombinant antigens recognized by L.7.15 antibody

Crude lysates containing antigens expressed by phage Y3179, T3181, Y3182 and Y3183 were prepared as described for Table 2. Responses of the T-cell clones to two lysate concentrations (10 μg ml^{-1} and 50 μg ml^{-1}) are given as in Table 1.

* Control cultures without antigen.

of an 18K *M. leprae* protein recognized by the monoclonal antibody L7.15 (refs 7, 8). Y3179 contains 3.2 kilobases (kb) of *M. leprae* DNA, sufficient to encode additional polypeptides that might be fortuitously expressed in the Y3179 lysate and which could conceivably be responsible for stimulation of the T-cell clones. However, two lines of evidence favour the idea that some portion of the 18K protein is responsible for T-cell stimulation. Additional λ gtll clones containing smaller inserts and sharing only 1.25 kb of DNA produce the epitope recognized by L7.15 (Fig. 1); *E. coli* lysates of these phage stimulate the same T-cell clones that respond to Y3179 (Table 3). More importantly, while most *M. leprae* proteins exhibit immunological cross-reactivity with proteins from other mycobacteria, the L7.15 epitope is specific to *M. leprae*[8,9], as is the response of the five *M. leprae*-specific T-cell clones. The precise nature of the stimulatory epitope is being investigated.

These results establish that vaccination of normal volunteers with killed *M. leprae* induced a population of CD4-positive T cells that could be cloned *in vitro* and which exhibited *M. leprae*-specific reactivity. In addition, T-cell clones from two volunteers were capable of responding to an *M. leprae* antigen expressed in crude λ gtll phage lysates of *E. coli*. This and possibly other *M. leprae* antigens recognized by T-cell clones may be relevant to protection against leprosy.

The methods used here should be generally applicable to the identification of parasite polypeptide antigens recognized by T cells. While there is a high background of nonspecific reactivity of normal peripheral blood lymphocytes to crude phage lysates, antigen-specific T-cell clones produce a relatively minor background response, making it possible to test their reactivity to individual antigens in crude lysates.

For leprosy, these methods should facilitate further identification and characterization of *M. leprae* antigens recognized by T cells. Once these antigens are purified, it should be possible to evaluate their relative importance to the T-cell repertoire of *M. leprae*-immune individuals and to examine their role in protection against infection.

We thank Drs T. M. Buchanan, A. H. J. Kolk, J. Ivanyi and O. Closs for anti-*M. leprae* monoclonal antibodies and J. L. Stanford, J. Convit, G. Rook, R. J. W. Rees, O. Closs and J. Bennedsen for mycobacterial antigens. Recombinant human interlerleukin-2 was kindly provided by Cetus. We also thank D. Baltimore, M. Gefter and N. Oliver for discussion and critical comments. Technical assistance was provided by Inger Natvig and D. Sweetser. Secretarial assistance was provided by Heidi Andersen. This work was supported by the UNDP/World Bank/WHO Special Programme for Research and Training in Tropical Diseases.

Leprosy displays a remarkable spectrum of symptoms correlating with the T-cell-mediated immune reactivity of the host against the causative organism, *Mycobacterium leprae*[1]. At one pole of this spectrum are lepromatous leprosy patients showing a *M. leprae*-specific T-cell unresponsiveness[2]; at the other are tuberculoid leprosy patients displaying both acquired immunity and delayed-type hypersensitivity against *M. leprae* which are thought to be conferred by helper T (T_h) cells[1,3–5]. Because well-defined *M. leprae* antigens are crucial for the prevention and control of leprosy[1,6,7], we have cloned *M. leprae*-reactive T cells (TLC) of the helper phenotype from a tuberculoid leprosy patient. As reported here, these TLC show an unexpected diversity in the recognition of *M. leprae* and related mycobacteria, which is different from that exhibited by monoclonal antibodies[8,9]. Half of these TLC are completely or almost *M. leprae*-specific, whereas the other half are cross-reactive with most or all other mycobacteria. A *M. leprae* protein of relative molecular mass (M_r) 36,000 (36K) defined by a *M. leprae*-specific monoclonal antibody[7,8,10] stimulates 4 out of 6 TLC tested. Each of these TLC recognizes a different antigenic determinant, one of which is *M. leprae*-specific. The previous paper describes other *M. leprae*-specific T-cell clones half of which recognize an epitope on a *M. leprae* protein of M_r 18 K.

Whereas the *M. leprae*-specific unresponsiveness in lepromatous leprosy patients may be triggered by specific immunosuppression-inducing determinants on the bacillus[11], virtually nothing is known about the antigens recognized by T_h cells responsible for the cell-mediated immune reactivity against *M. leprae* in tuberculoid leprosy patients. To study the antigenic determinants involved in activating these T cells in more detail, we have cloned *M. leprae*-reactive T cells of a tuberculoid leprosy patient.

Peripheral blood mononuclear cells of a tuberculoid leprosy patient were restimulated *in vitro* with *M. leprae* antigen, cloned and propagated as described elsewhere[12]. Autologous Epstein-Barr virus (EBV)-transformed B cells (EBV-BC) were used as antigen-presenting cells (APC), as evidence suggests that these cells can effectively present *M. leprae* antigens to primed T cells (for review see ref. 13). One advantage of using EBV-BC as APC is that such cells provide a continuous and unlimited source

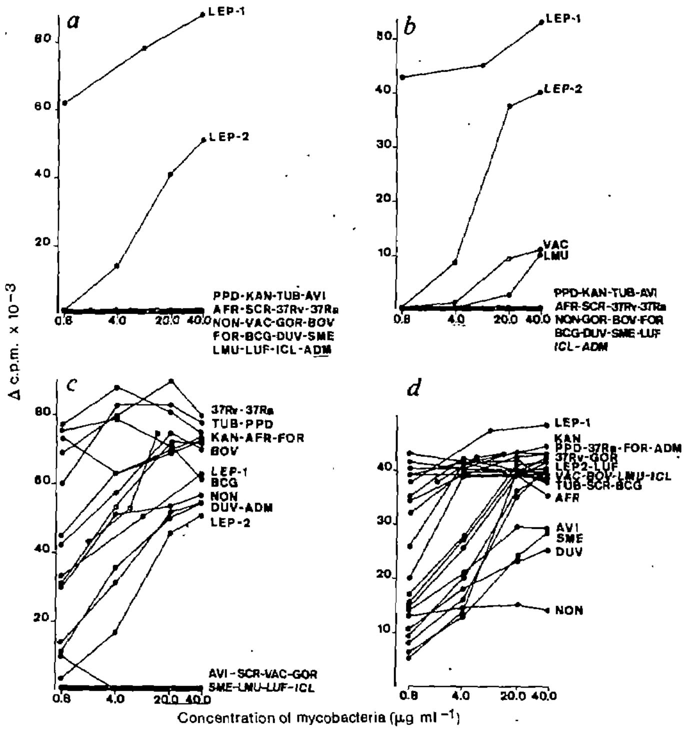

Fig. 1 Antigen specificity of *M. leprae*-reactive cloned T cells. Mycobacterial antigens were presented via autologous or HLA class II-compatible APC to 23 different *M. leprae*-reactive TLC from a tuberculoid leprosy patient. Four different patterns of reactivity were observed, and a representative example of each pattern is shown (*a–d*) (pattern *a*: $n=6$, *b*: $n=5$, *c*: $n=2$, *d*: $n=10$). The antigens tested were: LEP-1, Dharmendra lepromin, consisting of bacilli isolated from human lepromas; LEP-2, armadillo-derived *M. leprae*; PPD, purified protein derivative of *M. tuberculosis* (obtained from Statens Serum Institute, Copenhagen); KAN, *M. kansasii*; TUB, *M. tuberculosis*; AVI, *M. avium*; AFR, *M. africanum*; SCR, *M. scrofulaceum*; 37Rv, *M. tuberculosis* H37Rv; 37Ra, *M. tuberculosis* H37Ra; NON, *M. nonchromogenicum*; VAC, *M. vaccae*; GOR, *M. gordonae*; BOV, *M. bovis*; FOR, *M. fortuitum*; BCG, *M. bovis* BCG; DUV, *M. duvalii*; SME, *M. smegmatis*; LMU, *M. lepraemurium*; LUF, *M. lufu*; ICL, *M. avium intracellulare*; ADM, armadillo-derived aspecific mycobacteria. Dharmendra lepromin was tested in dilutions of 1:240, 1:120 and 1:60. PPD was tested at concentrations of 1.7, 5.0 and 16.7 μg ml^{-1}. All other mycobacteria had been ultrasonicated as described in ref. 21, and were tested at 0.8, 4.0, 20.0 and 40.0 μg ml^{-1}. Results are mean Δ c.p.m. × 10^{-3} (^{3}H-thymidine incorporation) of duplicate cultures (standard deviations mostly <10%), as assessed by subtracting background proliferation in the absence of antigen from responses in the presence of antigen.

Methods. Antigen reactivation, cloning, expansion and proliferative assays were performed as described elsewhere[12]. Briefly, peripheral blood mononuclear cells were isolated by Ficoll-Isopaque density gradient centrifugation and restimulated *in vitro* with an optimal concentration of Dharmendra lepromin (1:120–1:60) in 24-well tissue culture plates. T-cell blasts, enriched for by Percoll density centrifugation, were then cloned by limiting dilution on a feeder cell mixture consisting of irradiated autologous EBV-BC (10^5 cells ml^{-1}), peripheral blood mononuclear cells from 3–4 random donors (10^6 cells ml^{-1}), and Dharmendra lepromin (1:120–1:60). Of the original 295 microwells seeded, 56 contained growing cultures, and 34 of these showed proliferative responses. Growing cultures were restimulated once a week with the feeder mixture, supplemented with Leuko Agglutinin A (1 μg ml^{-1}) (Pharmacia) and expanded in the presence of interleukin-2-containing supernatants. In proliferative assays, 10^4 TLC, 5×10^4 irradiated autologous or HLA class II-compatible peripheral blood mononuclear cells as APC, and antigen were co-cultured in flat-bottomed 96-well microtitre plates (Greiner, FRG). After 72 h, 1.0 μCi ^{3}H-thymidine was added to each well; cultures were collected 16 h later on glass-fibre filters using a semi-automatic sample harvester. ^{3}H-Tdr incorporation assessed by liquid scintillation counting.

Table 1 *M. leprae*-specific and cross-reactive TLC recognize different determinants on a 36K protein purified by a *M. leprae*-specific monoclonal antibody

	T cell:	1G5	1E4	2F9	3B4	1F9	3E8	TLB1	TLB2
Antigen	Antigen specificity:	LEP (*a*)*	LEP (*a*)	LEP-VAC-LMU (*b*)	Partly cross-reactive (*c*)	Completely cross-reactive (*d*)	Completely cross-reactive (*d*)		
M. leprae		14.2±4.3	57.9±0.1	88.4±6.2	42.2±2.1	10.0±2.0	70.5±3.5	53.7±5.0	46.7±0.9
36K *M. leprae* protein		0.1±0.0	24.0±5.5	26.8±0.5	21.4±0.6	0.2±0.0	20.0±0.2	18.2±4.9	17.2±3.4

Medium		0.0±0.0	0.1±0.1	0.1±0.1	0.2±0.1	0.1±0.0	2.3±1.8	0.1±0.1	0.3±0.0

The results are the mean c.p.m. ($\times 10^{-3}$) ± s.d. of duplicate cultures. Positive cultures are boxed and are defined as exceeding the mean background proliferation by at least 3×s.d. and in addition giving $>10^3$ c.p.m. Proliferation assays were carried out as described in Fig. 1 legend. *M. leprae* antigen is Dharmendra lepromin. The 36K protein was purified by the fast protein liquid chromatography system (FPLC; Pharmacia, Sweden) (P.R.K. *et al.*, manuscript in preparation). Briefly, *M. leprae* sonicate was applied to an anion-exchange column (Mono Q, HR5/5; Pharmacia) and eluted with a linear salt gradient. Further purification was carried out on a gel permeation column (TSK G3000 SW; LKB, Sweden). The purity of the antigen was analysed by SDS-polyacrylamide gel electrophoresis and SDS-polyacrylamide gel electrophoresis immunoperoxidase assay[11]. The 12K protein was purified by affinity chromatography using monoclonal antibody ML06A1 coupled to cyanogen bromide-activated Sepharose 4B, followed by elution with 3 M NaSCN[9]. The optimal stimulatory concentration for the 36K protein was 16 μg ml^{-1}, and that for the 12K protein, 0.4 μg ml^{-1}. TLB1 and TLB2 were generated as described in ref. 15.

* For abbreviations see Fig. 1 legend.

of APC, which drastically reduces the number of autologous peripheral blood mononuclear cells needed for the cloning and propagation of antigen-specific T cells.

Twenty-three *M. leprae*-reactive proliferative TLC were selected at random and studied in more detail with regard to their antigen specificity. All 23 TLC were of the $T3^+$ $T4^+$ $T8^-$ phenotype, and were strongly positive for HLA-DR antigens. Twenty-two TLC were restricted in their response by HLA-DR determinants and one was restricted by a hitherto unknown polymorphic HLA-DQ determinant, as assessed by panel and inhibition studies (T.H.M.O. *et al.*, manuscript in preparation).

Two *M. leprae* preparations of different origin, ultrasonicates from 19 other mycobacteria, and the purified protein derivative (PPD) of *Mycobacterium tuberculosis* were presented to these TLC via autologous or HLA (histocompatibility locus antigen) class II-compatible APC. The results (Fig. 1) reveal four patterns of antigen reactivity: (1) TLC recognizing determinants expressed exclusively by *M. leprae* ($n=6$); (2) TLC activated by determinants present on *M. leprae* and cross-reactive with one or two other mycobacterial strains, mainly *Mycobacterium vaccae* and *Mycobacterium lepraemurium* ($n=5$); (3) TLC reactive with several but not all mycobacteria ($n=2$); and (4) TLC triggered by cross-reactive determinants present on all mycobacteria, sometimes with the exception of *Mycobacterium nonchromogenicum* ($n=10$). None of the TLC showed a proliferative response in the presence of APC and either tetanus toxoid or *Candida albicans*, which represented non-mycobacterial control antigens. Similar data were obtained with TLC from two other patients (data not shown).

Recently, five *M. leprae* proteins have been described that contain *M. leprae*-specific antigens recognized by murine monoclonal antibodies[7-9,14]. The M_rs of these proteins are 12K, 18K, 28K, 36K and (55-)65K. To investigate whether these antibody-defined *M. leprae* proteins are also recognized by human T cells, we tested the 12K and 36K *M. leprae* proteins which had been purified by using, respectively, the *M. leprae*-specific monoclonal antibodies MLO6A1 (refs 8, 9) and F47-9-1 (refs 8, 10). Six different *M. leprae*-reactive TLC, and a *M. leprae*-generated polyclonal T-lymphoblast culture (TLB)[15] from the same patient (TLB1) and from a second tuberculoid leprosy patient (TLB2) were tested.

The data presented in Table 1 show that the *M. leprae*-specific 36K protein is recognized by four of the six TLC tested and by both TLB1 and TLB2, whereas the *M. leprae*-specific 12K purified protein is recognized by only one TLC and (weakly) by one TLB, each of which is also reactive with the 36K protein. As all four TLC reacting with the 36K protein display different antigen-specificity patterns (Fig. 1), they must recognize four different antigenic determinants on the 36K protein, only one of which is clearly *M. leprae*-specific. The finding that only one of the two *M. leprae*-specific TLC (1E4, see Table 1) recognized the 36K protein suggests that the other *M. leprae*-specific TLC tested (1G5) reacts with another *M. leprae*-specific determinant not expressed on the 36K protein. In addition, as only one of the two completely cross-reactive TLC (3E8) tested reacts with the 36K protein, at least two common mycobacterial determinants are defined by these TLC, one of which resides on the 36K protein.

The six TLC and the two TLB have so far failed to respond to 3,6-di-*O*-methylglucose-$(CH_2)_8$-bovine serum albumin (BSA), when tested at a wide range of concentrations (5×10^{-3}–2×10^3 μg ml^{-1}). This synthetic antigen contains a *M. leprae*-specific monosaccharide component which forms the terminal part of the trisaccharide complex on *M. leprae* phenolic glycolipid. This glycolipid has been shown to trigger *M. leprae*-specific suppressor T cells in lepromatous but not in tuberculoid patients, as measured by inhibition of concanavalin A-stimulated peripheral blood mononuclear cell cultures[13].

Thus, 6 out of 23 human helper TLC recognized at least two separate determinants that are uniquely expressed by *M. leprae*, but which are distinct from those defined by murine monoclonal antibodies, only a few of which have been found to recognize *M. leprae*-specific protein antigens[7-10,14]. So far, all murine *M. leprae*-reactive TLC cross-react with other mycobacteria[16,17]. The finding that 3 out of 5 nearly *M. leprae*-specific human TLC also react with *M. vaccae* is in accord with the results of *in vivo* skin tests which revealed a selective cross-reactivity between *M. leprae* and *M. vaccae*[18].

The TLC described here define antigenic determinants on purified *M. leprae* proteins which are capable of triggering T cells. It remains to be elucidated which *M. leprae* antigenic determinants recognized by these helper TLC are involved in protective immunity as opposed to immunopathology. A comparison of the antigenic determinants defined by TLC from healthy contacts with those defined by TLC from tuberculoid leprosy patients may be helpful in distinguishing between the two groups of *M. leprae* antigens. In addition to these two groups, a third group of antigens may be involved in the induction of *M. leprae*-specific suppression[6,11]. Recently, we have cloned *M. leprae*-reactive suppressor T cells. Thus, we will be able to study whether different antigenic determinants are recognized by cloned helper and suppressor T cells.

Thus the use of TLC and purified *M. leprae* proteins will enable us to define the *M. leprae* antigens involved in T-cell-mediated protective immunity, immunopathology and possibly suppression; these, therefore, are exquisite tools for the rational design of a *M. leprae* vaccine and skin-test reagents[1,6].

The T-cell responses against these proteins cannot be inhibited by the relevant monoclonal antibodies (data not shown); this was not unexpected because, as a rule, antibodies and T cells react with different epitopes of the same antigen (see, for example, ref. 19). It is interesting that four out of the six TLC and both TLB react with the 36K protein, whereas only one of these TLC and one TLB respond to one of the four other *M. leprae*-specific proteins known—that is, the 12K protein. This result suggests that T_h cells preferentially recognize immunodominant antigenic determinants[20] expressed on the 36K protein. Recently, the genes for the major proteins of *M. leprae* have been cloned and expressed[7] and indeed the five abovementioned *M. leprae*-specific proteins have been formed. Therefore, it should now be possible to determine whether one or more of the antigenic determinants on the 36K protein defined by these TLC is formed—in part—by lipid or carbohydrate components.

We thank Dr R. J. W. Rees and the late Dr C. C. Shepard for providing us with *M. leprae* antigens; Dr D. L. Leiker for his help in obtaining blood samples from leprosy patients; Arend Kolk and Frits Koning for monoclonal antibodies; Teunis Eggelte for synthetic saccharide antigens; John Haanen and Earl Johanns for technical assistance; and Tiny van Westerop for drawing part of the figure and preparing the manuscript. This study was supported in part by the Foundation for Medical Research (FUNGO grant 13-83-01), the Immunology of Leprosy (IMMLEP) component of the UNDP/WORLD Bank/WHO Special Programme for Research and Training in Tropical Diseases, and the Netherlands Leprosy Relief Association (NSL).

Note added in proof: Recent experiments show that analysis of a recombinant 36K *M. leprae*-specific protein, expressed in *Escherichia coli*, reveals that different *M. leprae*-specific protein determinants are detected by these *M. leprae*-specific TLC.

Identification of a secretory granule-binding protein as caldesmon

Robert D. Burgoyne, Timothy R. Cheek & Kathryn-Marie Norman

MRC Secretory Control Group, The Physiological Laboratory, University of Liverpool, PO Box 147, Liverpool L69 3BX, UK

Stimulation of adrenal chromaffin cells results in a rise in the concentration of intracellular free calcium[1-3] which initiates catecholamine secretion by exocytosis[4,5]. An understanding of the molecular basis of exocytosis will require knowledge of the sites of action of calcium. A role for calmodulin has been implicated in secretion from chromaffin cells[6,7], and isolated granule membranes bind both calmodulin[8] and a series of cytosolic proteins[9-12] in a calcium-dependent fashion. Here, we demonstrate that one of the cytosolic granule-binding proteins with a relative molecular mass (M_r) of 70,000 (70K) is a form of the calmodulin-regulated actin-binding protein caldesmon, first isolated from smooth muscle[13]. Cytoplasmic gels assembled from an adrenal medullary extract in the absence of Ca^{2+} contained actin and the 70K protein. The association of both of these proteins with the cytoplasmic gel was inhibited by a micromolar concentration of Ca^{2+}. In addition, we have demonstrated that the 70K protein is localized at the periphery of chromaffin cells. These results are consistent with the notion that 70K protein (caldesmon) has a role in regulating the organization of actin filaments of the cell periphery during the secretory process.

A number of bovine medullary cytosolic proteins bind to chromaffin granule membranes with a range of affinities for Ca^{2+} (refs 9-12). Among those that bind with the highest affinity (Fig. 1*a*, *b*) is a polypeptide with an approximate M_r of 70,000. This major granule-binding protein was used as an immunogen in the preparation of specific antisera (Fig. 1). Anti-70K antiserum recognized the 70K polypeptide on immunoblots of granule-binding proteins (Fig. 1*c*) and adrenal medulla homogenates. In immunoblots of homogenates of a variety of rat tissues, anti-70K antiserum recognized a 70K polypeptide in brain, pancreas, heart and liver but not in skeletal muscle (Fig. 1*f*–*i*). An additional 130K polypeptide was recognized by anti-70K antiserum in brain and liver. A non-immune mouse antiserum did not recognize any polypeptides on immunoblotting. The 70K polypeptide in the adrenal homogenate (Fig. 1*d*, *e*) and the granule-binding protein fraction, and the 70K and 130K polypeptides recognized by anti-70K in brain homogenates, were found to be heat-stable.

The protein caldesmon was first isolated from chicken gizzard as a 150K calmodulin-binding F-actin regulatory protein[13]. Subsequently, caldesmon was shown to be present in a range of tissues and cell types[14,15] but absent from skeletal muscle[14]. Caldesmon is now known to exist in a 120–140K form and a 71–77K form; both forms bind to calmodulin and F-actin and are heat-stable[15,16]. There is a remarkable similarity between these caldesmon forms and the polypeptides recognized here by anti-70K, including the ability of 70K from the granule-binding preparation to bind to calmodulin[11]. That the 70K and 130K proteins are forms of caldesmon was confirmed by the finding that anti-70K recognized the purified turkey gizzard 140K caldesmon on immunoblotting (Fig. 2*a*, *b*).

Extracts from adrenal medulla incubated at 25 °C in the absence of Ca^{2+} form supramolecular cytoplasmic gels. Using peptide mapping in comparisons with skeletal muscle proteins, we have shown that actin and myosin are major constituents of these gels (our unpublished observations). Gels assembled from extracts containing $>1\ \mu M$ free Ca^{2+} were depleted of both actin and a 70K polypeptide (Fig. 2*c*–*i*). Immunoblotting with

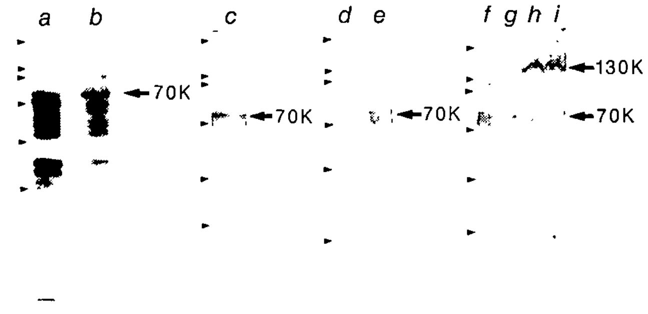

Fig. 1 Characterization of anti-70K antiserum. Granule-binding proteins were prepared[9] by binding from bovine medullary cytosol in the presence of 1 mM Ca^{2+} and elution at 100 μM free Ca^{2+} (*a*), followed by elution with EGTA (*b*). *c–i*, Immunoblotting with anti-70K antiserum of: granule-binding protein fraction, eluted with EGTA (*c*), and the heat-precipitated (*d*) and heat-stable (*e*) fractions of bovine adrenal medullary homogenate; and homogenates of rat heart (*f*), pancreas (*g*), liver (*h*) and brain (*i*). Differences in the apparent migration of the 70K polypeptide between gels are due to differences in electrophoretic conditions. In each case the positions of M_r markers are indicated by arrowheads on the left (M_r, from the top: 205K, 116K, 94K, 67K, 43K and 29K). **Methods.** Anti-70K antiserum was prepared by excising gel bands from tracks of granule-binding proteins as in *b*. The gel slices were homogenized in phosphate-buffered saline (PBS) and injected into mice with Freund's complete adjuvant three times, with intervals of 14 days between injections. The mice were killed and bled 14 days after the last injection and a γ-globulin fraction prepared from the serum by sodium sulphate precipitation. Antisera produced in two different mice gave essentially identical results. For immunoblotting, proteins were separated on 10 or 12.5% polyacrylamide slab gels and transferred to nitrocellulose sheets. After staining the proteins with Ponceau S, the nitrocellulose was washed in PBS, incubated in 3% bovine serum albumin (BSA), 0.2% Triton X-100 in PBS for 10 min, then incubated overnight at 4 °C with anti-70K (1:50 dilution). Bound antibody was detected by incubation with anti-mouse biotin (diluted 1:50; Amersham) for 60 min, followed by incubation with horseradish peroxidase (HRP)-streptavidin (diluted 1:150; Amersham) for 30 min and development with diaminobenzidine. All antibodies were diluted in 3% BSA, 0.2% Triton X-100 in PBS. Homogenates were prepared by homogenization in 5 mM Tris-HCl, 4 mM EGTA, *p*H 8.0 and 180 μg protein was electrophoresed per track. Adrenal medullary homogenate was boiled for 3 min before separation, by centrifugation, into heat-precipitable and heat-stable fractions.

anti-70K demonstrated that the antiserum recognized the Ca^{2+}-regulated 70K polypeptide of the gel as well as a minor 130K polypeptide (Fig. 2*k*, *l*); this provides additional confirmation that the 70K protein is the actin-binding protein caldesmon and demonstrates that the assembly of actin and 70K into supramolecular gels is inhibited by micromolar Ca^{2+} concentrations.

The localization of 70K in bovine adrenal chromaffin cells was determined by immunoperoxidase staining of bovine chromaffin cells in primary culture (Fig. 3). The cultures also contained flat non-chromaffin cells[17] which showed weak, diffuse staining with anti-70K. In chromaffin cells, anti-70K antiserum produced intense staining of regions at the cell periphery. We have also found that on cryostat sections anti-70K stains the periphery of rat adrenal chromaffin cells as well as cells from a wide range of other tissues (R.D.B. and K.-M.N., unpublished observations). Anti-70K stained stress fibres in fibroblasts in culture[15,18] and gave a pattern of staining in small intestine that was indistinguishable from that described for antibody to gizzard caldesmon[14]. The localization of 70K in chromaffin cells resembles that of α-fodrin[19], which suggests that these two proteins may form part of a subplasmalemmal cytoskeleton. However, α-fodrin was localized as a continuous ring around the cell periphery in control cells and as patches following stimulation, whereas 70K was already localized along patches of the cell periphery in control cells (Fig. 3). We detected no effect of stimulation on the localization of 70K in chromaffin cells.

Thus, we have demonstrated that a protein isolated on the basis of its ability to bind reversibly to chromaffin granule membranes in the presence of Ca^{2+} is a form of the actin-binding protein caldesmon. Furthermore, caldesmon and actin assemble from adrenal medullary extracts into supramolecular gels only when the free Ca^{2+} concentration is <1 μM. It has been shown previously that, in the absence of Ca^{2+}, caldesmon stimulates actin assembly[20], crosslinks F-actin[16] and inhibits the regulation of F-actin gelation by filamin[21,22]. All these functions of caldesmon are inhibited by Ca^{2+} in the presence of calmodulin, to which caldesmon then binds preferentially[13,16,20,22]. In the adrenal chromaffin cell, caldesmon may be expected to control a reorganization of F-actin at the cell periphery, including solation of the subplasmalemmal actin network following the rise in intracellular free Ca^{2+} concentration during stimulation.

A role for changes of cytoskeletal organization in secretion from chromaffin cells has previously been suggested from the observations that chromaffin granules bind F-actin[23] and increase the viscosity of F-actin in a Ca^{2+}-inhibitable manner[24]

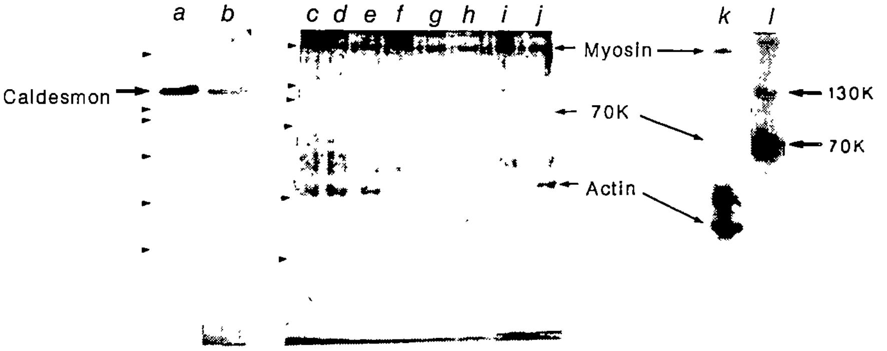

Fig. 2 Recognition by anti-70K antiserum of turkey gizzard caldesmon and a Ca^{2+}-regulated protein in medullary cytoplasmic gels. Turkey gizzard 140K caldesmon was transferred to nitrocellulose and revealed by Ponceau S staining (*a*) and immunoperoxidase staining with anti-70K (*b*). Cytoplasmic gels assembled from medullary extracts in the presence of 0.1 (*c*), 0.5 (*d*), 1.0 (*e*), 2.5 (*f*), 5.0 (*g*), 7.5 (*h*) or 10 μM (*i*) free Ca^{2+} or EGTA (*j*) are shown on a Coomassie blue-stained gel, and in the presence of EGTA after transfer to nitrocellulose and staining by Ponceau S (*k*), followed by anti-70K (*l*). The positions of M_r markers are indicated by arrowheads on the left (M_r, from the top: 205K, 116K, 94K, 67K, 43K, 29K).

Methods. Caldesmon was prepared from turkey gizzard as described previously[16]. For the preparation of cytoplasmic gels, adrenal medullae were homogenized in 1 mM EDTA, 10 mM mercaptoethanol, 0.5 mM ATP, 40 mM Tris-HCl *p*H 7.4 and centrifuged at 100,000*g* for 90 min at 4 °C. Aliquots were dialysed against 5 mM EGTA, 10 mM mercaptoethanol, 0.5 mM ATP, 40 mM Tris-HCl *p*H 7.0, with $CaCl_2$ added to give a calculated free $[Ca^{2+}]$ of 0.1–10 μM. Cytoplasmic gels were assembled after addition of $MgCl_2$ to 8 mM by incubation at 25 °C for 60 min, harvested by centrifugation at 13,000*g* for 7 min at room temperature, and contaminating membranous material was removed by washing with buffer containing 0.5% Triton X-100.

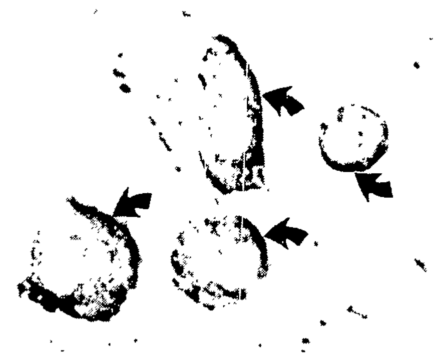

Fig. 3 Immunoperoxidase staining of bovine chromaffin cells in primary culture by anti-70K antiserum. Non-chromaffin cells in the culture[17] were only weakly stained. Chromaffin cells (arrowed) have intense staining around the internal periphery of the cells which in most cases does not form a continuous ring.

Methods. Bovine adrenal chromaffin cells were dissociated and maintained in monolayer culture for 2 days as described previously[17], after which they were fixed with 4% formaldehyde in PBS and air-dried. After washing in PBS, immunoperoxidase staining with anti-70K antiserum was done using essentially the same conditions as those used for immunoblotting (see Fig. 1 legend).

and that stimulation of chromaffin cells results in a redistribution of α-fodrin[19]. Of importance for future investigations is the relationship between caldesmon and α-fodrin at the cell periphery during exocytosis. The demonstration of a reversible association of caldesmon with granule membranes suggests an additional function for caldesmon in regulating the interaction of secretory granules with the cytoskeleton during the secretory process.

Estimation of the polarity of the protein interior by optical spectroscopy

Robert B. Macgregor[*] **& Gregorio Weber**

Department of Biochemistry, School of Chemical Sciences,
University of Illinois, Urbana, Illinois 61801, USA

Crystallographic studies of myoglobin have shown that the haem pocket is lined with nonpolar amino-acid residues[1]. In order to estimate the true polarity of the interior of proteins, certain studies have used bound fluorophores[2–7], the spectroscopic properties of which reflect the polarity of their environment. These studies have most often used 1-amino-8-naphthalene sulphonate (ANS) as a probe, but a more suitable probe, in principle, is 6-propionyl 2-(*N*,*N*-dimethyl)aminonaphthalene (PRODAN)[8]. We have synthesized a molecule with the advantageous spectroscopic properties of PRODAN but with a higher affinity for apomyoglobin: 2′-(*N*,*N*-dimenthyl)amino-6-naphthopyl-4-*trans*-cyclohexanoic acid (DANCA), and report here its use to determine the polarity of the myoglobin haem pocket. Our results show that the pocket is actually a polar environment, and the polarity can be accounted for by peptide amide dipoles.

Polar chromophores and fluorophores are molecules that exhibit large differences in the electronic distribution of the ground and fluorescent states. The local polarity of a biological system harbouring such molecules can be estimated by comparison of the spectral properties in that environment with those of the probe in solvents of known polar characteristics. The ideal polar fluorescent probe should have no sources of charge besides two readily identifiable monopoles, and the dipole moment that they determine should change strength but not direction in the excited state. Most important, the probe should be soluble in a range of solvents that cover the polarity scale, from apolar solvents like cycohexane to the most polar ones like alcohol or water. PRODAN is a fluorophore probe which approaches this standard (Fig. 1); its synthesis and spectral properties have been described elsewhere[8]. The positive monopole resides at the amino nitrogen and the negative one at the keto oxygen. The dipole moment in the ground state is ~2 D and that of the fluorescent state 18-20 D. In cyclohexane the absorption and emission are centred at 341 and 401 nm respectively, in water they are located at 364 and 531 nm. The absorption and emission bands in water are much broader than in cyclohexane.

Attempts to observe the changes in spectra that result when PRODAN is bound to apomyoglobin are hampered by the relatively low affinity of this molecule for this binding site. To improve the binding affinity while keeping the spectral characteristics of PRODAN intact, we synthesized DANCA (Fig. 1 and G.W. and F. J. Farris, unpublished data). The negatively charged carboxyl was introduced to improve the affinity for the apoprotein, following the example of haem itself, while the cyclohexane ring was intended to hold the carboxyl group away from the spectrally relevant aminoaphthoyl moiety. This isolation reveals itself in the spectral identity of PRODAN and DANCA in media in which their common solubility permits comparison.

At 24 °C apomyoglobin binds one DANCA molecule with $K_D = 1.2 \times 10^{-5}$ M. Bound DANCA is stoichiometrically displaced by the addition of one equivalent of haemin, indicating a unique location in the haem pocket of myoglobin[3]. The absorption spectrum of the protein-dye complex (Fig. 1) is centred at 362 nm (27,620 cm^{-1}) and has a halfwidth of 2,790 cm^{-1}. Cooling the sample to 4 °C shifts the absorption to 366 nm (27,320 cm^{-1}) and causes it to narrow to 2,480 cm^{-1}. The spectrum of DANCA in buffer is centred at 360 nm (27,780 cm^{-1}), with a halfwidth of ~3,600 cm^{-1} and no appreciable temperature dependence. In cyclohexane the absorption of PRODAN is centred at 341 nm (29,326 cm^{-1}) and has a halfwidth of 2,100 cm^{-1}. The shift in absorption with respect to cyclohexane is direct evidence of the considerable polarity of the haem pocket. The temperature dependence of the absorption indicates

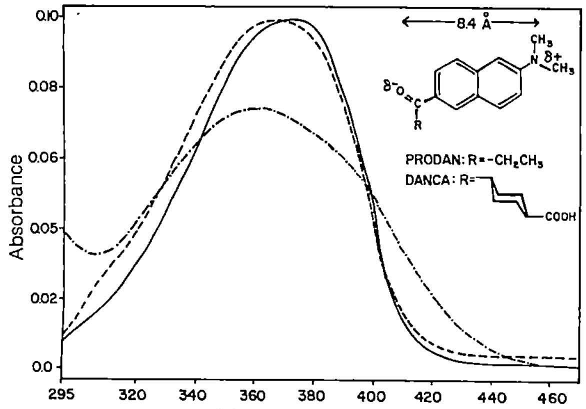

Fig. 1 The absorption spectra of a solution containing 200 μM apomyoglobin and 5.7 μM DANCA (95% bound) at 4 °C (——) and at 24 °C (- - -). Also shown is the absorption spectrum of a 5.7-μM solution of DANCA in buffere at 24 °C -·-·-). Inset: structure of PRODAN and DANCA. DANCA was synthesized in this laboratory; purity was verified using HPLC. The concentration of DANCA in water was determined spectrophotometrically using $E = 14{,}000\ \text{cm}^2\ \text{mmol}^{-1}$ at 360 nm. Haemin and sperm whale myoglobin were purchased from Sigma. Apomyoglobin was prepared according to the method of Teale[13]. All experiments involving protein were carried out in 20 mM bis-Tris buffer, *p*H 6.0. Before an experiment, the apomyoglobin was centrifuged at 20,000 *g* at 4 °C for 40 min to remove aggregates. The concentration of apomyoglobin was determined from the absorbance at 280 nm using $E = 13{,}500\ \text{cm}^2\ \text{mmol}^{-1}$ (ref. 14).

that the population becomes more heterogeneous with increasing temperature. This can result from small changes in the binding site or from the appearance of new fluorophore orientations in an unchanged binding site. Regardless of origin, it is clear that the bound dye has, at either temperature, a much narrower distribution of interactions than in the aqueous buffer.

The fluorescence of DANCA in *p*H 6.0, 20 mM bis-Tris buffer at room temperature has an average wavenumber of 18,826 cm^{-1} (531 nm). On titration with apomyoglobin, this fluorescence is replaced by a new one centred at 21,755 cm^{-1} (459 nm) (Fig. 2) and the intensity increases by a factor of four. This emission spectrum is almost identical to those of PRODAN or DANCA in *N*,*N*-dimethylformamide (DMF) at room temperature[8] or in a glycerol at −40 °C[9,10]; it is also strongly redshifted with respect to the fluorescence spectra in nonpolar media like cyclohexane (401 nm), or weakly polar ones like chloroform (440 nm) or even acetone (452 nm).

The heterogeneity of the probe interaction is revealed by the dependence of the fluorescence spectrum on the excitation wavelength and the changes in interaction in the excited state are revealed by its temperature dependence[9,10]. Figure 3[9] shows the average fluorescence energy and bandwidth of PRODAN in glycerol as a function of excitation wavelength at −42 °C and at 1 °C. At the lower temperature, glycerol is a vitrified solid and its interactions with the dye at emission are determined by the ground state charge distribution about the fluorophore. In this condition, excitation at the longer wavelengths selects fluorophore populations possessing more favourable energies of interaction with solvent and therefore results in progressively redder emissions; the fluoroscence excited at the red edge of the absorption shows the largest shift and the smallest bandwidth. At the higher temperature, 1 °C, the rate of solvent dipole reorientation exceeds the rate of emission and causes the fluorescence spectrum to become almost independent of the excitation wavelength. The emission of DANCA-apomyoglobin (Table 1) also shows dependence on excitation wavelength but, in contrast to the data in Fig. 3, the spectral changes are not diminished by raising the temperature within the range in which the protein remains in its native conformation.

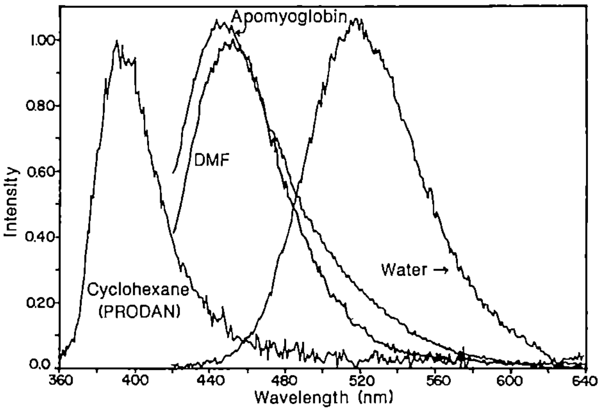

Fig. 2 The fluorescence of DANCA bound to apomyoglobin and in three solvents of different polarity.

The dependence of the fluorescence spectrum on the exciting wavelength shows that we are dealing with a heterogeneous population of DANCA-apomyoglobin complexes, although occupation is restricted to a single molecule. This result is not surprising as haem itself binds in two orientations within its pocket[11].

At 24 °C, the absorption of DANCA-apomyoglobin is shifted −1,706 cm^{-1} and the emission −2,751 cm^{-1} with respect to the corresponding values of PRODAN in cyclohexane. In the complete absence of relaxation of the polar surroundings, we expect equal displacements of the absorption and emission with respect to those observed in an apolar solvent like cyclohexane. The observed difference discloses the existence of a relaxation that increases the Stokes shift expected in a rigid medium by about −1,000 cm^{-1} and is substantially complete at 4 °C. Its course at lower temperatures was explored by observations of the fluorescence of DANCA-apomyoglobin in 60% glycerol-aqueous buffer. We found that the characteristic spectrum of DANCA-apomyoglobin at room temperature is not disturbed by addition of glycerol. At −34 °C the spectral relaxation observed in buffer at higher temperatures is reduced to −200 cm^{-1} and at −74 °C it has disappeared altogether.

Table 1 Dependence of the fluorescence of DANCA bound to apomyoglobin on excitation wavelength

Excitation (nm)	Low temperature* $\Delta\bar{\nu}_g$	Low temperature* Halfwidth	High temperature* $\Delta\bar{\nu}_g$	High temperature* Halfwidth
359	21,818	1,652	21,755	1,707
427	21,119	1,552	20,985	1,636
Difference	−699	−100	−770	−71

All energies are given in wavenumbers (cm^{-1}).

* At 359 nm, low temperature is 4 °C and high temperature is 24 °C; on excitation at 427 nm, low temperature is 6 °C and high temperature is 22 °C.

We draw two conclusions from our observations. First, the protein provides a polar environment that induces a shift in the average absorption of ~ −1,700 cm^{-1} with respect to the unperturbed absorption of the probe; this environment is therefore quantitatively similar to that observed in solutions of PRODAN or DANCA in DMF. At −74 °C the fluorescence is similarly displaced. Second, a relaxation process takes place during the excited state and results in an additional redshift of the fluorescence of ~1,000 cm^{-1}. It is already incipient at −35 °C and virtually complete at 4 °C.

The origin of the relaxation is obscure; however, it seems clear that the time-independent effects on the absorption, and the emission of the probe at the lowest temperature can be

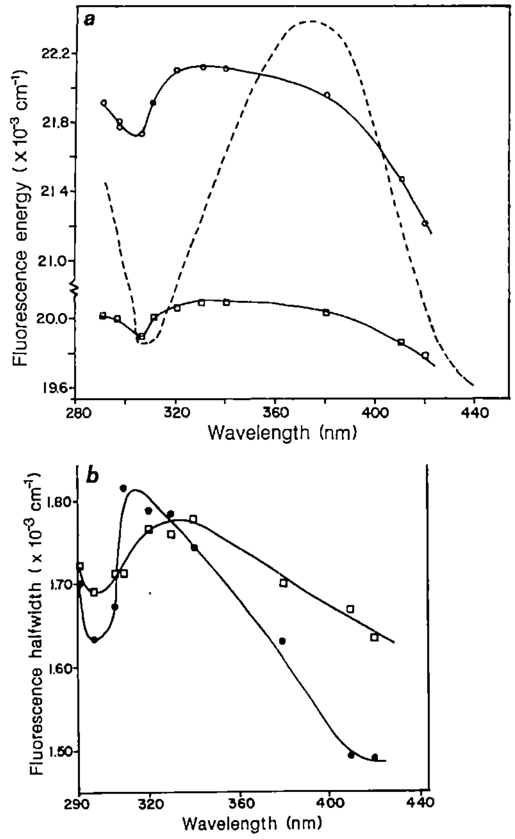

Fig. 3 The excitation wavelength dependence of the emission of PRODAN in glycerol at two temperatures. *a*, Average energy of the fluorescence against excitation wavelength at −42 °C (○) and 1 °C (□). The fluorescence excitation spectrum of PRODAN in glycerol at −42 °C is given by the broken line. *b*, Fluorescence bandwidth against excitation wavelength at −42 °C (●) and 1 °C (□). All fluorescence spectra were recorded on a modified version of the single-photon counting spectrofluorimeter described by Jameson *et al.*[15], and were corrected for monochromator transmission and photomultiplier tube response. The fluorescence spectra of the DANCA-apomyoglobin complex were deconvolved from the total spectra, which included contributions from free DANCA, by using a nonlinear least-squares fitting procedure[16].

explained in terms of discrete electrostatic interactions between the probe and protein and that the strength of these interactions corresponds to a medium of considerable polarity. This result is at variance with previous conclusions on the polarity of the haem pocket based on the ANS-apomyoglobin complex[3]. We note that the virtual insolubility of ANS in truly nonpolar solvents excludes the possibility of establishing a reliable polarity scale for this probe. Additionally, the absorption spectrum and the effect of temperature on the absorption and emission were not evaluated.

Crystallographic studies of myoglobin have shown that the haem pocket is lined with nonpolar amino-acid residues[1], yet our results indicate that the binding site is strongly polar. This inconsistency is only apparent; the fluorophore monopoles can readily interact with the protein amide dipoles through the low dielectric medium provided by the nonpolar amino acids. As a direct test of this supposition, we have calculated the electrostatic interaction energy of DANCA with the partial charges at each of the nitrogen and oxygen atoms of the peptide backbone. In this calculation it was assumed that the probe molecule is located in the plane defined by the haem in the crystallographic structure of deoxymyoglobin and that the coordinates of the other atoms in the molecule are unchanged when the haem is substituted by the probe molecule. Figure 4 shows a contour map of calculated interaction energies of the peptide bond

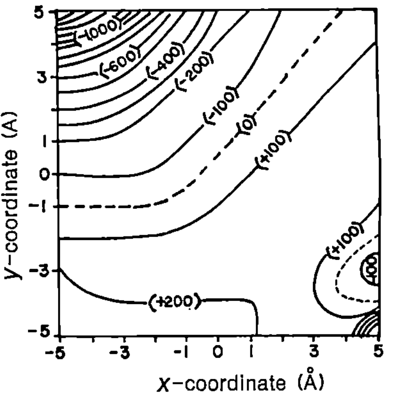

Fig. 4 Map of the electrostatic interaction energy of the peptide bond dipoles with a partial charge located in the plane occupied by the haem in the crystallographic structure of deoxymyoglobin. The partial charge equals the charge of the positive monopole of DANCA in the excited electronic state (∼−0.56 e) minus its charge in the ground state (∼−0.06 e); the strength of the DANCA monopoles follows from the known dipole moments in ground and excited state, 2 and 18 D, respectively, and the distance between the monopoles, 8.4 Å. The x-coordinate is the direction defined by a line drawn from Fe^{2+} and N-1 of the porphyrin ring, the y-coordinate is along the line between Fe^{2+} and N-2, and the z-coordinate is perpendicular to the ring. The energies are given in units of cm^{-1} to facilitate comparison with the spectroscopic results. Contour lines represent changes of 100 cm^{-1} in the interaction energy. Energies were calculated assuming a dielectric constant of 3 for the interior of the protein, and a dipole moment of 3.7 D for the peptide bond.

charges with a positive monopole successively placed at the nodes of an 11 × 11-Å grid situated in the haem plane. A dielectric constant of 3 was assumed for the intervening medium. The contour lines show calculated differences between the electrostatic interaction energies of all the protein peptide dipoles with the amino nitrogen of DANCA, in both the ground and excited states, expressed in wavenumbers to permit direct comparison with the spectral shifts. The values for the negative monopole (DANCA keto oxygen) are equal in magnitude but with opposite sign. For each position that can be chosen as a location for the amino nitrogen of the probe, the total change in interaction energy on excitation equals the energy shown at that point plus the negative of the energy at a point placed 8.4 Å away. Several probe orientations yield spectral displacements well in excess of −1,000 cm^{-1}. These values are close to the difference between the absorption of DANCA-apomyoglobin at room temperature or that of the emission at −74 °C, and the respective values for PRODAN in cyclohexane. However, we do not wish to stress the coincidence of observation and calculation; no exact calculation could be made without knowing the atomic structure of the DANCA-apomyoglobin complex. Our intention here is to demonstrate qualitatively the contribution of the peptide bonds to the polarity of the interior of proteins rather than to analyse particular properties of myoglobin.

Warshel *et al.*[12], in re-examing the theories concerning the interactions of charges located within proteins, point out that the similarity of the dissociation constants of proton-bearing groups within the protein and in water force the conclusion that the protein is polar in their immediate vicinity, and that previous theoretical treatments had neglected the role of peptide bonds in the stabilization of charges. Our results corroborate these considerations by demonstrating that a large portion of the polarity registered by a spectroscopic probe placed in the haem pocket of myoglobin must be attributed to the peptide dipoles.

We thank Dr George Phillips for providing us with the crystallographic coordinates of deoxymoglobin. This work was supported in part by PHS grant GM 11223.

Human N-*myc* is closely related in organization and nucleotide sequence to c-*myc*

N-*myc*, a cellular gene related to the c-*myc* proto-oncogene[1-4], was originally identified on the basis of its very frequent amplification and overexpression in a restricted set of tumours, most notably human neuroblastomas[1,2]. That N-*myc* may have a causal role in the genesis of these tumours is suggested by the observation that in the rat embryo fibroblast co-transformation assay[5,6] it has a transforming potential similar to that of c-*myc*[7,8]. The apparent structural and functional homology of N-*myc* and c-*myc* suggests that they may be members of the same proto-oncogene family. However, despite these apparent similarities, expression of the two genes appears to be dramatically different with respect to tumour specificity, as well as tissue and developmental stage specificity[9,10]. To further elucidate the common and unique aspects of N-*myc* and c-*myc* gene structure and function in normal and transformed cells, we have determined the organization of human N-*myc* and the nucleotide sequence of its messenger product, and we report here that N-*myc* and c-*myc* have a similar intron/exon structure and that their protein products share regions of significant homology.

To isolate an N-*myc*-specific complementary DNA clone, we prepared a λ phage Charon 16A cDNA library from total poly(A)$^+$ RNA of the IMR-32 human neuroblastoma cell line and screened the library for hybridization to various N-*myc* genomic probes. Initial screenings with the N-*myc* genomic probe NB-19-21 which derives from the more 5′ region of the gene (see Fig. 1*a*) yielded no clones. Thus, we isolated a genomic clone containing regions of the gene both 5′ and 3′ to NB-19-21 (Fig. 1*a*), identified restriction fragments from the 3′ portions which contained coding sequences but not repetitive sequences, and used these to further screen the library. This approach yielded multiple N-*myc*-specific cDNA clones, the longest of which was ~1 kilobase (kb) (pI1-1; Fig. 1*b*). To obtain longer cDNA sequences we hybridized a primer prepared from pI1-1 (Fig. 1*b*) to mRNA from the human neuroblastoma cell line NB-16, extended the primer with reverse transcriptase, prepared a Charon 16A library of the primer-extended cDNA, and screened the resulting library with NB-19-21 (see Fig. 1 legend). In this way we isolated an additional cDNA clone, p9D (Fig. 1*b*), which when combined with pI1-1 represents 1.7 kb of unique sequence.

Attempts to extend primers isolated from the 5′ end of clone 9D were unsuccessful due to a strong stop in the reverse transcription reaction; various analyses indicated that this strong stop resulted from extensive secondary structure in this region of the sequence (see Fig. 2). To bridge this strong stop, we used S_1 nuclease mapping (fragments 7,7′ and 8; see Fig. 1*c*) to identify coding sequences in the corresponding region of the genomic clone. A primer isolated from these coding sequences (a 500-base pair (bp) *Xho*I-*Bam*HI fragment from NB-19-21; Fig. 1*a*) was hybridized to NB-16 mRNA, extended and cloned. Screening the library with a 1-kb *Bam*HI-*Eco*RI genomic fragment shown by S_1 nuclease analysis to contain N-*myc* coding sequences (BR-1; Fig. 1*a*) yielded several clones, the longest of ~1 kb (p0; Fig. 1*b*). Colinearity of these cDNA sequences with the mRNA was confirmed by S_1 nuclease protection experiments (probes 1-5; Fig. 1*c*). Together, the cDNA clones and the genomic fragment bridging them represent 2.7 kb of unique sequence, almost enough to encode the entire N-*myc* message (~3.0 kb). Additional transcribed sequences lie upstream of the 5′ end of the cDNA clone (see below).

Comparison of the nucleic acid sequence of the N-*myc* cDNA and genomic clones, coupled with various S_1 nuclease mapping experiments, indicated that N-*myc* has three exons; in analogy to c-*myc* gene, we refer to these exons as 5′-exon 1-exon 2-exon 3-3′ (Fig. 1*a*). Figure 2 shows the nucleotide sequences of the N-*myc* cDNA clones and of selected regions of the genomic clone containing sequences complementary to N-*myc* mRNA (as defined by S_1 protection). The presence of a poly(A) tail and an adenylation signal confirms the orientation of the genomic and cDNA clones and defines approximately the 3′ terminus of the N-*myc* gene (Figs 1*a*, *b*, 2).

Restriction endonuclease mapping and Southern blot analyses (data not shown) indicate that the 5′ portion of the 9D cDNA clone spans a discontinuous region in the genomic clone. Comparison of the nucleotide sequence of this region of the cDNA clone with the relevant regions of the N-*myc* genomic clone confirms that sequences contiguous in cDNA are separated by an intron of ~2,500 bp in the genomic clone (Figs 1*a*, *b*, 2). That this discontinuity was not a cloning artefact was confirmed by appropriate S_1 nuclease protection experiments (using fragment 8 in Fig. 1*c*). The sequences CAG/GTAAAG, spanning the 3′ boundary of exon 2, and TCTTTCTCTCAG/AT, spanning the 5′ boundary of exon 3, are in agreement with the predicted consensus sequences for the donor and acceptor splice junctions[11]. Extensive restriction endonuclease analyses (not shown) confirm the colinearity of the cDNA and genomic clone within the proposed exon 3 sequence. Thus, exon 3 extends for 1,526 bp between the splice site and the poly(A) tail (Fig. 2). The 5′ boundary of exon 2, located by S_1 nuclease protection analyses, lies ~170 bp 5′ to the *Xho*I site within the NB-19-21 region (analyses used fragments 7 and 7′ of Fig. 1*c*); the exact boundary (nucleotide 680, Fig. 2) was determined by comparing the nucleotide sequences of the corresponding regions of the genomic clone and cDNA clone p0. Thus, exon 2 extends 902 bp from this upstream boundary to the 3′ splice donor site. The sequences TTGCAG/TGT, spanning the 5′ boundary of exon 2, and CCG/GTGCGT, spanning the 3′ boundary of exon 1, correspond respectively to the acceptor and donor splice junction consensus sequences[11]. Sequences in the 5′ cDNA clone p0 extend 314 bp upstream of the splice donor site at the 3′ boundary of exon 1.

Because S_1 nuclease protection experiments (using fragment 6 of Fig. 1*c*) indicated that additional transcribed sequences lie upstream of the end of this clone, we used primer extension to define the 5′ boundary of exon 1. Primer extension of a *Nar*I fragment isolated from the 5′ end of p0 (nucleotides 309-375;

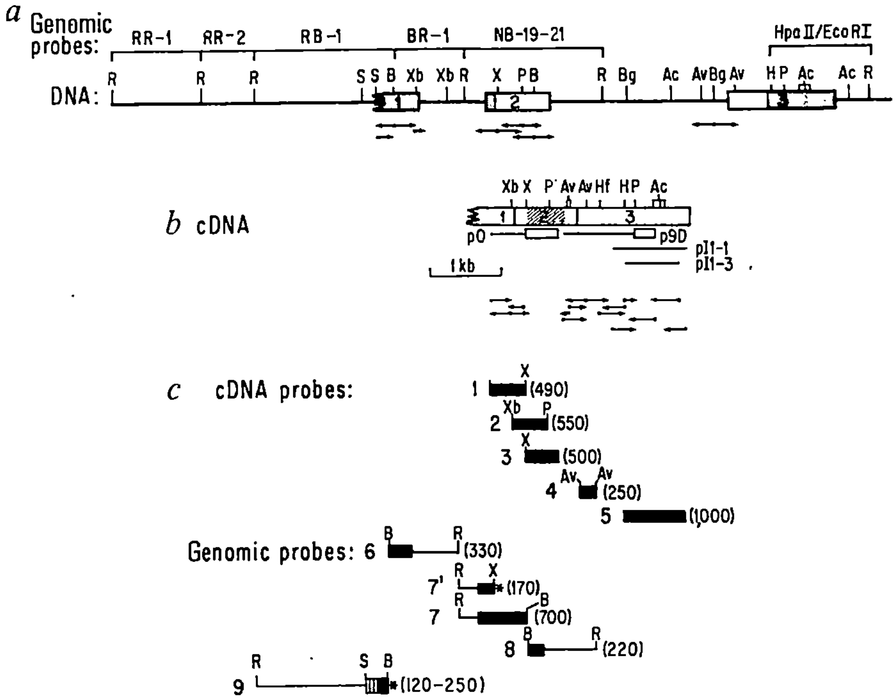

Fig. 1 Organization of human N-*myc*. *a*, Partial restriction map of the N-*myc* genomic clone NG-2. Boxes are exons: shaded boxes denote untranslated sequences, open boxes translated sequences. The heterogeneity of the 5′ terminus of exon 1 is indicated by sawtoothing. Genomic fragments used as probes to screen the cDNA libraries and in Northern blot analyses are indicated at the top. Arrows below the map indicate genomic fragments that have been sequenced. Restriction sites: Ac, *Acc*I; Av, *Ava*I; B, *Bam*HI; Bg, *Bgl*II; H, *Hin*cII; Hf, *Hin*fI; P, *Pst*I; R, *Eco*RI; S, *Sma*I; X, *Xho*I; Xb, *Xba*I (not all sites are shown). *b*, Partial restriction map of the N-*myc* cDNA. Open box denotes the structure of the N-*myc* cDNA deduced from the cDNA clones, S_1 nuclease mapping of relevant regions of the genomic clone and primer extension. The numbers within the boxes indicate the positions of the three exons. The shaded area within exon 2 represents the region of composite cDNA derived from genomic coding sequences; the stippled area in exon 1 represents the region derived by primer extension and S_1 nuclease mapping. The heterogeneity of the 5′ end of the mRNA is indicated by sawtoothing. The cDNA clones are shown beneath the map. The boxed portion of cDNA clones p9D and p0 indicates the position of the primer used in the construction of these clones. Arrows indicate sequencing strategies. *c*, S_1 nuclease mapping of the coding regions of the genomic clone and of the cDNA clones. Fragments used as probes in the S_1 protection experiments are shown. The locations of the protected fragments are indicated by solid boxes; for probes 6 and 8, the location was confirmed by sequence analysis and cDNA cloning. For probe 9, the multiplicity of the protected fragments is indicated by a hatched box. The size of the protected fragment is given in parentheses. An asterisk at the end of a fragment indicates that the probe was terminally labelled; all other probes were uniformly labelled.

Methods. The N-*myc* genomic clone NG-2 was obtained by screening a Charon 35 recombinant phage library (prepared from size-fractionated, *Mbo*I partially-digested DNA[44] from the LA-N-5 human neuroblastoma cell line[45]) with the 2-kb *Eco*RI fragment NB-19-21 (ref. 1). cDNA clones pI1-1 and pI1-3 were isolated from a cDNA library[46] prepared from total poly(A)$^+$ RNA from the IMR-32 cell line[47] and screened with a 1.6-kb *Hpa*II-*Eco*RI fragment of the genomic clone which was shown to contain coding sequences but not repetitive sequences as follows. *Eco*RI fragments from the genomic clone 3′ of NB-19-21 were further digested with various restriction enzymes, the DNA fractionated on agarose gels and transferred to nitrocellulose. Duplicate blots were probed with either nick-translated human DNA (to detect repetitive sequences) or first-strand cDNA synthesized from RNA from the NB-16 human neuroblastoma cell line[48] (to detect coding sequences). cDNA clone 9D was derived as follows. A terminally labelled, single-stranded *Hae*III fragment isolated from pI1-1 (nucleotides 2,481–2,745 in Fig. 2) was used in a primer extension reaction[49] with cytoplasmic poly(A)$^+$ RNA[46] from the NB-16 cell line. This DNA/RNA hybrid was converted to double-stranded (ds) DNA[50] and cloned into the λ phage vector Charon 16A[46]. The library was screened with the NB-19-21 probe. The cDNA clone p0 was obtained by primer extension of a 500-bp *Xho*I-*Bam*HI genomic fragment (nucleotides 852–1,357 in Fig. 2) and cloning of the ds-cDNA as described above. The library was screened with the 1-kb *Bam*HI-*Eco*RI genomic fragment, BR-1. For S_1 nuclease mapping, fragments were subcloned into the M13 phage vector mp8 or mp19 and single-stranded, uniformly labelled DNA probes were prepared as described previously[51]. Alternatively, the DNA was terminally labelled after restriction endonuclease digestion and single-stranded probes were isolated from a strand separation gel[46]. Labelled probes were hybridized with 20–250 ng of NB-16 cytoplasmic poly(A)$^+$ RNA in 80% formamide, 400 mM NaCl, 40 mM PIPES *p*H 6.4, 1 mM EDTA at 42 °C or 50 °C overnight, and digested with 6,000 units S_1 nuclease (Boehringer). For pI1-1, the 1-kb *Eco*RI insert was subcloned into pSP64 and the plasmid linearized with *Pvu*II. Transcription, hybridization and RNase digestion were performed as described elsewhere[52], except that 20 μCi of ^{32}P-CTP (760 Ci mol^{-1}) was used in a 10-μl reaction containing unlabelled CTP at a final concentration of 30 μM. Protected fragments were analysed on 5% polyacrylamide/7 M urea sequencing gels.

Fig. 2) localized the upstream boundary of exon 1 at ~200 bp 5′ of the primer (data not shown). To define this boundary more accurately, we repeated the primer extension analysis with a primer from an even more 5′ region (a 91 bp *Hae*II-*Bam*HI fragment, nucleotides 167–257 in Fig. 2; Fig. 3*c*). Numerous bands of varying intensity extending 35–165 nucleotides 5′ of the primer were observed (Fig. 3*a*). S_1 nuclease analysis using genomic fragment RB-1 labelled at the *Bam*HI site (probe 9 of Fig. 1*c*; see Fig. 3*c*) yielded multiple protected fragments corresponding to those observed in the primer extension assay (Fig. 3*b*), demonstrating that these products represent multiple transcription initiation sites and not strong stops in the reverse transcription reaction. Identical fragments were protected by RNAs from a variety of human neuroblastoma cell lines in which N-*myc* is present in single and multiple copies (not shown), indicating that the heterogeneity of the 5′ end of exon 1 is not a result of amplification. Northern blot analysis using probes RR-1 and RR-2 (see Fig. 1*a*) failed to detect additional coding sequences in the 5′ region of the genomic clone (not shown). Thus, exon 1 appears to vary from 450 to almost 600 nucleotides long as a result of multiple sites of transcription initiation.

In summary, these data demonstrate that the N-*myc* gene is encoded by three exons. In support of this conclusion, it is notable that the combined size of the three exons is approximately enough to encode the entire N-*myc* mRNA, and the overall size of the N-*myc* gene (~7 kb) is consistent with the size predicted from transfection studies of the murine gene[7]. Thus, N-*myc* and c-*myc* appear to have a remarkably similar organization, the most prominent difference being the increased size of exon 3 (1.5 kb for N-*myc* as opposed to 0.9 kb for c-*myc*[12]; Fig. 2).

The apparent similarities in the organization of the N- and c-*myc* genes suggest the possibility of additional conserved features. Exon 1 of c-*myc* represents a long, untranslated leader sequence[13–16]. Although the exon 1 of N-*myc* contains two potential translation initiation codons (nucleotides 385 and 521; Fig. 2), termination codons in all three reading frames render it untranslatable. Thus, the N-*myc* and c-*myc* genes appear to have in common a large untranslated first exon (Fig. 2). Furthermore, it has been suggested that regulation of c-*myc* expression is mediated by hairpin-loop structures within the first exon[13] or between exons 1 and 2 (ref. 15). In this regard, it is notable that numerous potential stem-loop structures with significant standard free energy changes exist between exons 1 and 2 and within exon 2 of N-*myc*, although none is exactly homologous to those found in c-*myc* (see Fig. 2 legend).

As translation of the c-*myc* protein initiates near the 5′ end of exon 2 (ref. 12), we searched for a translation initiation codon in the 5′ region of exon 2 of N-*myc*. We found three ATGs within this region, at positions 797, 821 and 830 (see Fig. 2), all within the same translational reading frame. From the first ATG within exon 2, an open reading frame continues for 1,392 nucleotides (allowing for proper splicing) before reaching the termination codon TAG at position 2,280. Multiple termination codons interrupt this sequence in the other two translational

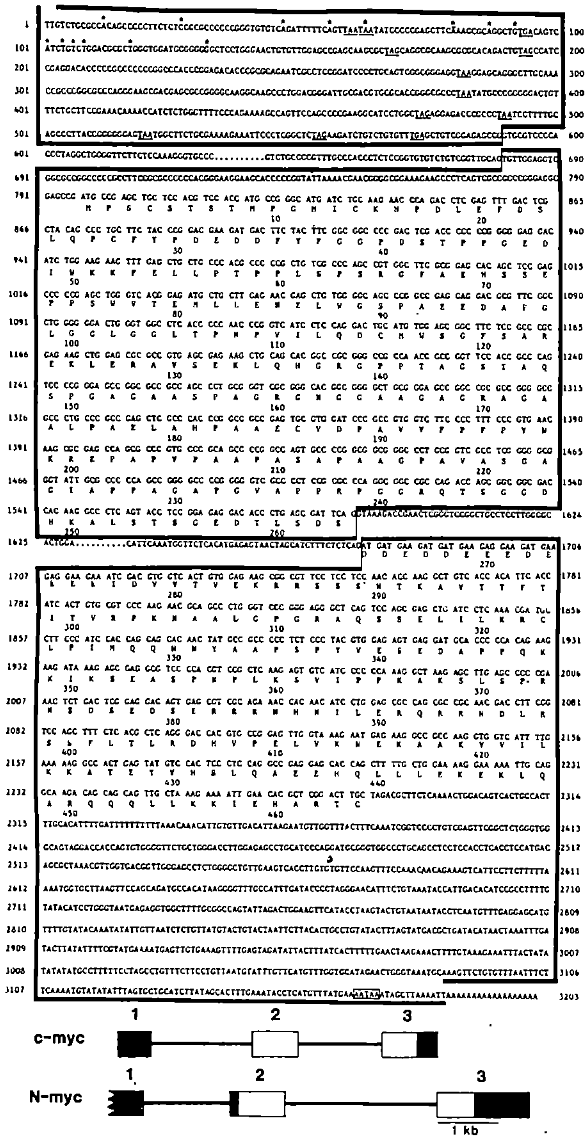

Fig. 2 Nucleotide sequence of human N-*myc*. Restriction fragments were isolated from the cDNA and genomic clones and terminally labelled. Sequencing was by the Maxam and Gilbert[53] method using the strategy described in Fig. 1*a*, *b*. Boxes around the sequence indicate the positions of the three exons; the open box defining exon 3 indicates that the precise 3′ end of the gene has not been determined. However, homology between human and murine genes in this region defines approximately the 3′ end of the gene. The open box around exon 1 indicates the heterogeneity of the 5′ boundary of this exon. Asterisks indicate transcription initiation sites; the locations of these sites, determined by primer extension and S_1 nuclease analyses, are accurate to within 5 bp. Gaps indicate regions of the introns that were not sequenced. The deduced amino-acid sequence of the putative N-*myc* protein is shown for nucleotides 797–2,279. The adenylation signal (AATAAA) is boxed[54]. Termination codons in exon 1 are underlined. Potential stem-loop structures in mature RNA were identified by computer analyses. The positions and free energy[55] of the 10 most stable structures are as follows (position indicated by the bases in the stem): 1,274–1,296 versus 1,413–1,439, $\Delta G_0 = -72.2\ \mathrm{kcal\ mol^{-1}}$; 211–231 versus 1,269–1,296, $\Delta G_0 = -65.6\ \mathrm{kcal\ mol^{-1}}$; 778–808 versus 1,198–1,227, $\Delta G_0 = -55.7\ \mathrm{kcal\ mol^{-1}}$; 1,082–1,107 versus 1,230–1,257, $\Delta G_0 = -52.1\ \mathrm{kcal\ mol^{-1}}$; 689–715 versus 780–803, $\Delta G_0 = -51.1\ \mathrm{kcal\ mol^{-1}}$; 320–345 versus 958–983, $\Delta G_0 = -48.9\ \mathrm{kcal\ mol^{-1}}$; 110–141 versus 1,243–1,274, $\Delta G_0 = -47.1\ \mathrm{kcal\ mol^{-1}}$; 719–740 versus 1,362–1,387, $\Delta G_0 = -32.3\ \mathrm{kcal\ mol^{-1}}$; 799–821 versus 2,525–2,548, $\Delta G_0 = -31.7\ \mathrm{kcal\ mol^{-1}}$; 582–697 versus 1,513–1,552, $\Delta G_0 = -29.7\ \mathrm{kcal\ mol^{-1}}$. Several of these structures occur in the area of the strong stop to reverse transcription (near the 5′ end of cDNA clone p9D, at base 1,403). Additional evidence for secondary structure in exon 2 derives from heteroduplexing experiments and difficulty in sequencing the region. A region of nucleotide sequence homology (60–70%) between the N-*myc* and r-*fos*[21] and c-*fos*[20] genes occurs between nucleotides 1,677 and 1,712. A structural comparison of N-*myc* and c-*myc* is shown at the bottom of the figure. Exons are indicated by boxes: open boxes represent translated sequences, solid boxes represent untranslated sequences. Heterogeneity of the 5′ end of N-*myc* is indicated by sawtoothing. The genes are oriented 5′-exon 1-exon 2-exon 3-3′.

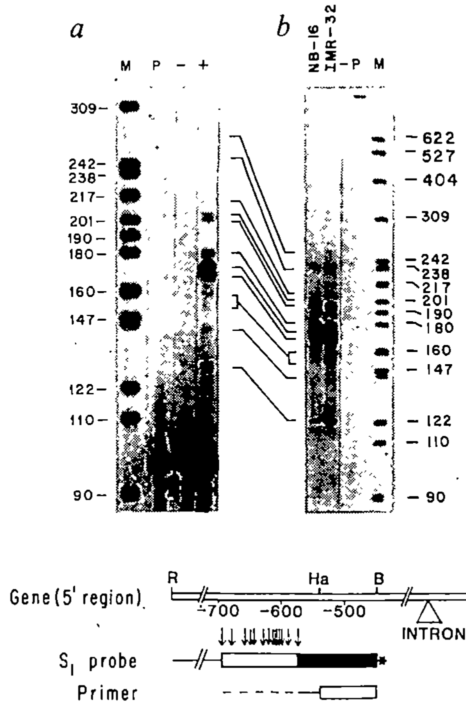

Fig. 3 Localization of the 5′ end of N-*myc*. *a*, Primer extension analysis. A 91-bp *Hae*II-*Bam*HI fragment isolated from the 3′ end of the genomic subclone RB-1 (nucleotides 167–257 in Fig. 2) was annealed to 2 μg of NB-16 cytoplasmic poly(A)$^+$ RNA and extended with reverse transcriptase[49]. *b*, S_1 nuclease mapping. Genomic fragment RB-1 labelled at the *Bam*HI site was annealed to 0.5 μg NB-16 cytoplasmic poly(A)$^+$ RNA or 25 μg of IMR-32 total RNA and digested with S_1 nuclease as described in Fig. 1 legend. The products of both assays (*a* and *b*) were analysed on 5% acrylamide/7M urea sequencing gels. Corresponding fragments in the two assays are indicated. Lane M, pBR322 DNA digested with *Hpa*II; P, probe; −, control reaction containing no RNA; + or NB-16, reaction containing NB-16 cytoplasmic RNA; IMR-32, reaction containing total RNA from the IMR-32 human neuroblastoma cell line. *c*, The 5′ end of N-*myc*, represented by the thin box. Numbering is with respect to the translation initiation signal, with the A of the ATG being +1. The probe used in the S_1 nuclease analysis is shown at the bottom. The protected fragment is indicated by a thick box; vertical arrows indicate the position of the 5′ termini. The primer used in the primer extension analysis is indicated by the open box beneath the probe. The extended products are indicated by the broken line. B, *Bam*HI; Ha, *Hae*II; R, *Eco*RI.

reading frames. Although we cannot say unequivocally that the ATG at 797 is the N-*myc* translation initiation codon, this seems likely because it is the first ATG of the open reading frame. In addition, this ATG initiation codon and the downstream coding sequence are conserved in murine N-*myc*[17].

Several observations indicate that the proposed N-*myc* coding region is correct, most notably the striking homology of the putative N-*myc* protein to the c- and v-*myc* proteins throughout their amino-acid sequences (discussed in detail below). In addition, *in vitro* translation of purified N-*myc* mRNA yielded a diffuse product of relative molecular mass (M_r) 50,000 (50K)–55K (data not shown), a size in accord with the M_r of 50K predicted from the nucleotide sequence of the putative N-*myc* coding region (Fig. 2). Thus, the putative N-*myc* protein is similar in size to the c-*myc* protein; the larger size of the N-*myc* mRNA appears to result primarily from its larger 3′-untranslated region (~900 bp compared with ~350 bp for the c-*myc* mRNA)[12].

Comparison of the deduced amino-acid sequence of the putative N-*myc* protein with that of the human and viral *myc* proteins indicates regions of significant homology in the domains encoded by both exons 2 and 3 (Fig. 4). When the protein products of N-*myc* and c-*myc* are compared with the product of the viral gene, the homology in both cases is higher in the exon 3-encoded domain. In the exon 2-encoded domain, the

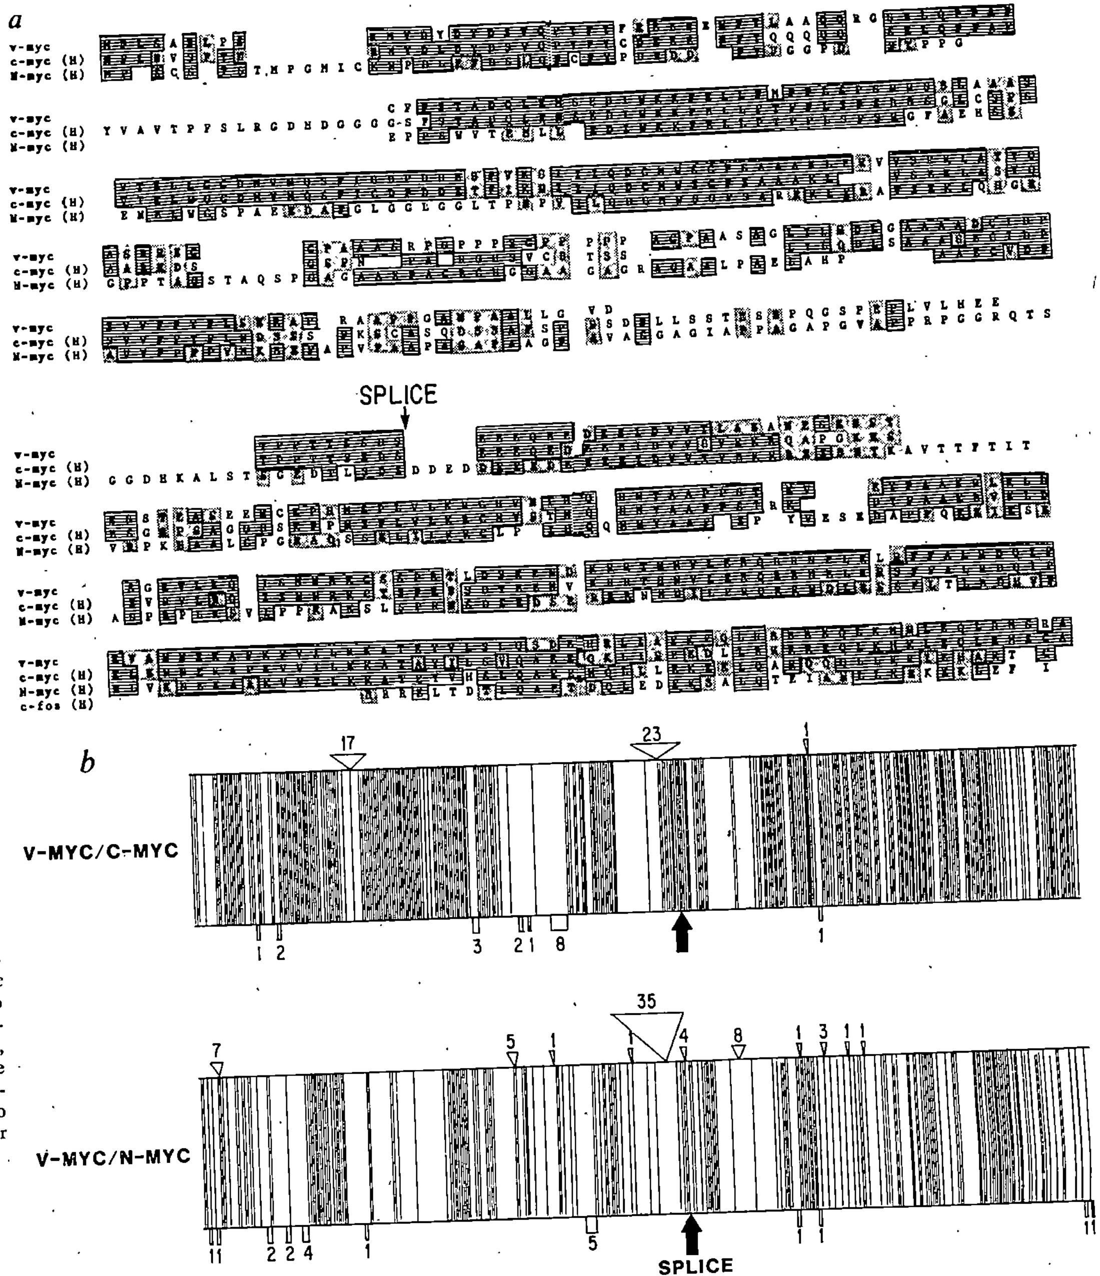

Fig. 4 Comparison of the amino-acid sequences of the putative N-*myc*, c-*myc* and v-*myc* proteins. ***a***, The amino acids were aligned by inspection, with gaps introduced to achieve maximum homology. Homologous amino acids are boxed and shaded. Amino-acid substitutions judged by McLachlan[56] to occur at higher than average frequencies are indicated by shading alone. The region of the human *fos* protein[20] found in a computer-assisted search of the 3,061 sequences in the NIH protein database (the Protein Identification Resources of the NIH) to be homologous with a region of the putative N-*myc* gene product is shown. The amino-acid sequence of the c-*myc* protein is from ref. 12; that of the v-*myc* protein from ref. 57. ***b***, Homology between amino-acid sequences of the v-*myc* protein and the c-*myc* and N-*myc* proteins is shown schematically. The sequence of the v-*myc* protein was used as a template on which either the N-*myc* or c-*myc* protein sequence was superimposed. Homologous amino acids are indicated by a line. Amino-acid insertions in the N-*myc* and c-*myc* proteins relative to the v-*myc* protein are indicated by triangles at the top, deletions by rectangles at the bottom of the grid; the numbers indicate the size, in amino acids, of the insertion or deletion.

homology between v-*myc* and c-*myc* is ~65%, that between v-*myc* and N-*myc* ~40%; in the exon 3-encoded domain these homologies are ~70% and 50%, respectively. A comparison of the v-*myc* and N-*myc* proteins (Fig. 4*b*) shows that there are clusters of highly conserved amino acids in both coding domains. Within the first protein-coding exon, c-*myc* diverges significantly from v-*myc* in three areas, including two large insertions and an 8-amino acid deletion[12]. In two of these regions N-*myc* more closely resembles v-*myc*; however, N-*myc* contains a 35-amino-acid insertion in the region where c-*myc* contains a 23-amino-acid insertion (see Fig. 4). In general, insertions and deletions of amino acids in N-*myc* relative to v-*myc* are in regions previously noted to be subject to such structural variations between *myc*-related proteins[18], in agreement with the notion that these are regions that can tolerate changes in length.

We have demonstrated that the structure of human N-*myc* resembles that of c-*myc* (Fig. 2), and that significant nucleotide and amino-acid sequence homology exists between these genes and between their gene products (Fig. 4). The data presented here support the notion that N-*myc* and c-*myc* are members of the same cellular proto-oncogene family[7]. c-*myc* encodes a nuclear protein which has DNA-binding capacity *in vitro*, a property attributed to the abundance of basic amino acids a the carboxy terminus of this protein[19]. This feature is share by the putative N-*myc* gene product; thus, the N-*myc* protei may also be a nuclear, DNA-binding protein. When the deduce amino-acid sequence of the N-*myc* protein was compared wit those of the over 3,000 proteins in the NIH protein database the most significant region of homology detected (excluding v and c-*myc* genes) was between the putative N-*myc* and c-*fo* proteins: when residues 425-464 of the predicted N-*myc* protei are aligned with residues 157-196 of the c-*fos* protein[20], 15 c the 40 amino acids are homologous, with many other conserva tive substitutions (Fig. 4). In addition, a region of notab nucleotide sequence homology between the N-*myc* and r-*fos* and c-*fos*[20] genes occurs at the beginning of exon 3 (see Fig. legend). Although any significance of these homologies remai to be determined, it is notable that the c-*fos* protein has al been localized to the nucleus[22].

In addition to the structural and functional similariti between the *myc* genes and their respective products, so regulatory similarities have also been observed, most notab the reduced expression of the N- and c-*myc* genes in certa tumour lines following chemical differentiation[23-26]. Howev other aspects of the regulation of the two genes appear to be drastically different. The c-*myc* gene product is expressed in a wide variety of normal and transformed cells where it is probably involved in growth and division[23,27-30]. In addition, deregulated expression of c-*myc* has been implicated as contributing to the development of numerous classes of tumours[31-35]. However, expression of N-*myc* is detectable in a very restricted set of normal or transformed cells and deregulated expression of N-*myc* has been implicated only in a limited set of tumours[9,10]. Neither the control nor the function of the differences in expression of the two *myc* genes is understood. However, it is notable that the promoter regions of the two genes appear to differ. Whereas transcription of c-*myc* mRNA initiates at two cap sites located ~150 bp from one another, each of which is preceded by a classical TATA motif[13-16], transcription of N-*myc* mRNA appears to initiate at multiple sites, most of which occur in the absence of an upstream TATA-like sequence. Such initiation heterogeneity has also been observed for the dihydrofolate reductase[36] and 3-hydroxy-3-methylglutaryl coenzyme A reductase (HMG CoA reductase)[37] genes and for the early and late regions of simian virus 40 (SV40)[38,39]. Significantly, sequences upstream of the major N-*myc* initiation sites show several similarities to the promoter of SV40. This region is G+C-rich (~70% G+C) and contains a 9/10-nucleotide match with the imperfect 21-bp repeat of the SV40 promoter, including the hexanucleotide CCGCCC, which is important in transcription of the viral early and late genes[40-42]. This 'GC' motif has also been observed in the promoter of the herpes thymidine kinase gene[43] and in the control region of several housekeeping genes including HMG CoA reductase[37]. An additional property that the HMG CoA reductase[37] gene has in common with N-*myc* and c-*myc*[13-16] is the presence of an exceptionally long 5'-untranslated leader sequence, most of which derives from a 5' noncoding exon. The strong conservation of the 5' noncoding exon between the c-*myc* genes of mouse and human suggests a significant functional role for this exon: one proposed function is a regulatory role with respect to c-*myc* expression[13,15,31]. Although no homology is detectable between the 5' exon of N-*myc* and that of c-*myc*, the 5' exons of human and murine N-*myc* show 85% homology (not including insertions and deletions)[17]; this evolutionary conservation of the 5' exon of N-*myc* also suggests a significant functional role for the exon (in analogy to c-*myc* this may be a regulatory role). If so, the lack of homology between the 5' exons of N-*myc* and c-*myc* would be consistent with divergent regulatory patterns of the two genes.

MATTERS ARISING

Mapping of general anaesthetic target sites

FRANKS and Lieb[1] have suggested that the comparative effectiveness as general anaesthetics of members of the *n*-alkane and *n*-alkanol homologous series may be understood in terms of their effects on the activity of a water-soluble protein, firefly luciferase. In particular, they propose the following: "When general anaesthetic target sites in animals and the luciferase protein are mapped out using the fine details of the potency data, remarkable similarities are revealed'. We disagree. Consider first the *n*-alkane results. Figure 2 of Franks and Lieb indicates that roughly equal aqueous concentrations of *n*-pentane, *n*-hexane, *n*-heptane and *n*-octane are required for 50% inhibition of luciferase activity. However, there are data available on the effectiveness of these compounds as general anaesthetics. The data of Fuhner (see Table 4 of Ferguson[2]) and Crisp *et al.*[3] on alkane-induced narcosis in mice and barnacle larvae respectively show very clearly (given knowledge of the saturated aqueous concentrations[4]) that in both these widely disparate species, the effective aqueous concentration decreases progressively from *n*-pentane to *n*-octane; this is shown here in Fig. 1*a*. Thus alkane activity as a general anaesthetic and as an inhibitor of firefly luciferase could be said not to correlate at all.

For the *n*-alkanol system, Franks and Lieb compare luciferase data with their chosen combination of data from the studies of Vernon[5] and Meyer and Hemmi[6] on anaesthesia in tadpoles. These three sets of results are plotted in their original form in Fig. 1*b* (the plots have been displaced from each other vertically so as to show more clearly the variations in slope which are to be compared). The data of Meyer and Hemmi show no correlation with the luciferase results. The usefulness of Vernon's much earlier results is marred by the fact that, for the C_5 experiment, Vernon used not *n*-pentanol but an isopentanol of unspecified structure (perhaps even a mixture of the two isopentanols) and arbitrarily divided his result by two. The correct position of this point (shown in parentheses in Fig. 1*b*) is thus unclear, a feature which Franks and Lieb do not mention. Given also that Vernon says nothing about the purity of his *n*-alkanols—which, in 1913, was probably not very high—such correlation as might be claimed between the luciferase data and Vernon's results is, to say the least, unconvincing, and does not justify Franks and Lieb's Fig. 3.

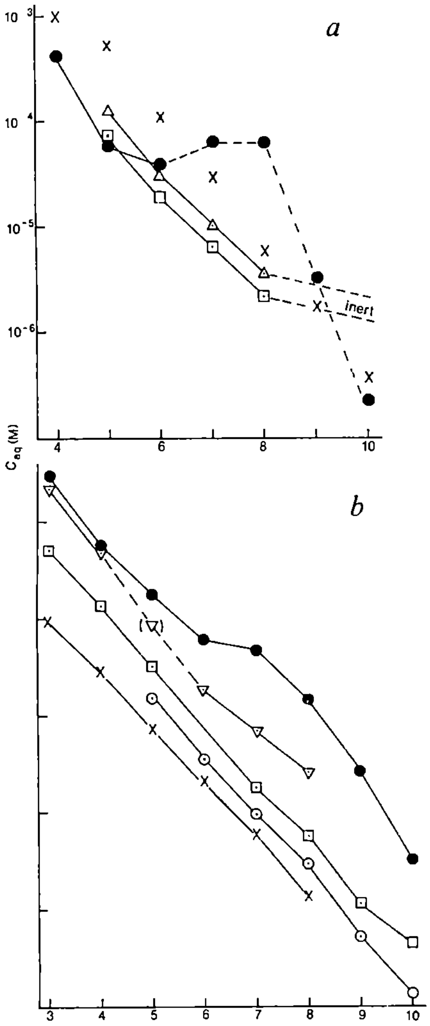

Fig. 1 The dependence on chain length of aqueous concentrations of *n*-alkanes (*a*) and *n*-alkanols (*b*) required to produce a given endpoint in various systems. The abscissa shows the number of carbon atoms in the molecule. The ordinate for *a* gives the aqueous concentrations (C_{aq}) of *n*-alkane required to produce a saturated solution in pure water[1] (×); inhibit luciferase activity by 50%[1] (●); induce narcosis in mice[2] (△), and induce narcosis in barnacle larvae[3] (⊡). The data for mice are given as the concentration in Ringer's solution at 20 °C which would be in equilibrium with the blood of the mouse. The ordinate for *b* again gives the required concentrations but the plots for each system have been displaced vertically to an arbitrary extent in order that the slopes may be more readily compared. The systems are: ●, 50% reduction of luciferase activity[1]; ∇, reversible suppression of spontaneous movement in tadpoles (the point in parentheses is derived from data for an undefined iso-derivative)[5]; ⊡, reversible suppression of reflex movement in tadpoles[6]; ⊙, 50% reduction of Na current in a voltage-clamped squid giant axon[7]; ×, reversible inhibition of luminescence in bacteria[8].

While their relevance to general anaesthesia is debatable, similar experiments examining the effects of alcohols on the sodium current of the squid giant axon[7] and on bacterial luminescence[8] (Fig. 1*b*) show no significant irregularities in the range pentanol to heptanol and exhibit clear similarities to the data of Meyer and Hemmi on anaesthesia in tadpoles.

For the two families of *n*-alkanes and *n*-alkanols there remains the one similarity that, for the alkanols, the anaesthetic potency and the binding to luciferase decline beyond *n*-dodecanol. But there is thought to be little luciferase in the central nervous system.

FRANKS AND LIEB REPLY—We disagree with the criticisms of Elliott and Haydon. The purpose of our paper[1] was to demonstrate that the abrupt cut-offs in general anaesthetic potencies observed when ascending homologous series of *n*-alkanes and *n*-alcohols can be mimicked by a pure soluble protein, thus lending further support to the idea that the primary target sites in general anaesthesia are proteins. These cut-offs occur at very different positions in the alkane and alcohol series, when anaesthetic ED_{50} (50% effective dose) concentrations become greater than saturated aqueous concentrations.

For the *n*-alkanes, we found[1] that the luciferase cut-off occurs between C_6 and C_7. In animals, the cut-off point is species-dependent[1], occurring between C_6 and C_{10}. In view of the different cut-off positions, it is quite wrong to expect a point-to-point correlation in potency data in this transition region: Elliott and Haydon are comparing (luciferase) data just past the cut-off with (animal) data just before the cut-off. They have also ignored data for fish, which show a cut-off very similar to that for luciferase[1]. What is important is that the luciferase enzyme exhibits an alkane cut-off at a position similar to those observed in animals.

For the *n*-alcohols, we found that, in common with general anaesthesia, the luciferase cut-off occurs much later than it does for the *n*-alkanes and this is due to a levelling-off of ED_{50} s for the higher alcohols. These points are clear from Fig. 2, where data for general anaesthesia and luciferase inhibition are compared directly. (Elliott and Haydon have obscured these points by choosing to plot only data between C_3 and C_{10} and by offsetting their curves on a relative scale. Also, their inclusion of data for bacteria and squid axons seems to us a red herring.) The close correspondence between the data of Vernon[2] and those of Meyer and Hemmi[3] shows that the worries of Elliott and Haydon are unfounded. As for the inflection at about C_6, it is clear that, although small, it is a real feature of the combined general anaesthesia data. (Elliott and Haydon's concern about Vernon's C_5 data point is not relevant, as the same feature is found even if this is disregarded.) However, this minor feature has no bearing on the mechanism of the alcohol cut-offs, which are due to the much larger changes in slope at about C_{11}.

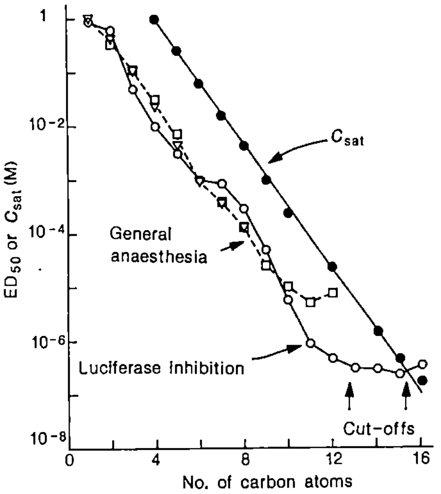

Fig. 2 The effectiveness of the *n*-alcohols as general anaesthetics and as inhibitors of firefly luciferase. ○, ED_{50} s for luciferase[1]; ∇ and □, general anaesthesia ED_{50} s for tadpoles, from refs 2 and 3, respectively; ●, maximum aqueous concentrations (solubilities)[4].

In summary, we feel that, in contrast to lipid bilayers, protein pockets similar to that found on firefly luciferase provide both a plausible and an economic explanation of cut-off effects in general anaesthesia. Despite our disagreements with Elliott and Haydon, we can at least concur with their final sentence!

N. P. FRANKS
W. R. LIEB
Biophysics Section,
The Blackett Laboratory,
Imperial College of Science
and Technology,
London SW7 2BZ

1. Franks, N. P. & Lieb, W. R. *Nature* **316**, 349-351 (1985).
2. Vernon, H. M. *J. Physiol., Lond.* **47**, 15-29 (1913).
3. Meyer, K. H. & Hemmi, H. *Biochem. Z.* **277**, 39-71 (1935).
4. Bell, G. H. *Chem. Phys. Lipids* **10**, 1-10 (1973).

BOOKS RECEIVED

Mathematics

Functions and Graphs: A Precalculus Course. By RAYMOND A. BARNETT. *McGraw-Hill: 1985. Pp.644. ISBN 0-07-003896-1. £27.95.*

Handbook of Applicable Mathematics, Vol. V, Parts A & B. Combinatorics and Geometry. WALTER LEDERMANN and STEVEN VAJDA (eds). *Wiley: 1985. Part A, pp.327, ISBN 0471-90567-4. Part B, pp.732, ISBN 0-471-90568-2. Complete set £88.*

A History of Algebra; From al-Khwarizmi to Emmy Noether. By B.L. VAN DER WAERDEN. *Springer-Verlag: 1985. Pp.271. Hbk ISBN 3-540-13610-X. DM 98.*

The Mathematics of Finite Elements and Applications, Volume V. J.R. WHITEMAN (ed.). *Academic: 1985. Pp.650. Hbk ISBN 0-12-747255-X. $59.00, £53.00.*

Mathematics and the Search for Knowledge. By MORRIS KLINE. *Oxford University Press: 1985. Pp.257. Hbk ISBN 0-19-503533-X. £21.00.*

Partial Differential Equations for Scientists and Engineers, 3rd Edn. By G. STEPHENSON. *Longman: 1985. Pp.161. ISBN 0-582-44696-1. £6.95.*

Recursive Aspects of Descriptive Set Theory. By RICHARD MANSFEILD and GALEN WEITKAMP. *Oxford University Press: 1985. Pp.144. ISBN 0-19-5036026. £15.*

Astronomy

Astronomy and the Imagination: A New Approach to Man's Experience of the Stars. By NORMAN DAVIDSON. *Routledge & Kegan Paul: 1985. Pp.237. ISBN 0-7102-0371-3. £12.95.*

The Milky Way Galaxy. HUGO VAN WOERDEN, RONALD J. ALLEN and W. BUTLER BURTON (eds). *Reidel: 1985. Pp.660. Hbk ISBN 90-277-1919-5; pbk ISBN 90-277-1920-9. Hbk Dfl. 195, $69; pbk Dfl. 90, $32.50.*

Stargazing: Astronomy Without a Telescope. By PATRICK MOORE. *Barrons: 1985. Pp.176. ISBN 0-8120-5644-2. $19.95.*

Space Science

From Spacelab to Space Station. H. STOEWER and PETER M. BAINUM (eds). *American Astronautical Society: 1985. Pp.259. Hbk ISBN 0-87703-209-2; pbk ISBN 0-87703-210-6. Hbk $50; pbk $40.*

Interstellar Migration and the Human Experience. BEN R. FINNEY and ERIC M. JONES (eds). *University of California Press: 1985. Pp.354. Hbk ISBN 0-520-05349-4. Hbk $28.75, £21.25.*

Permanent Presence — Making it Work. IVAN BEKEY (ed.). *American Astronautical Society: 1985. Pp.177. Hbk ISBN 0-87703-207-6; pbk ISBN 0-87703-208-4. Hbk $40; pbk $30.*

Spacefarers of the '80s and '90s. The Next Thousand People in Space. By ALCESTIS R. OBERG. *Columbia University Press: 1985. Pp.238. Hbk ISBN 0-231-05906-X. $24.95.*

Technology

Advances in Solar Energy: An Annual Review of Research and Development. KARL W. BÖER *et al.* (eds). *American Solar Energy Society/Plenum: 1983. Pp.310. ISBN 0-306-42019-8. Np.*

Pop-11: A Practical Language for Artificial Intelligence. By R. BARRETT. A. RAMSAY and A. SLOMAN. *Ellis Horwood: 1985. Pp.232. Pbk ISBN 0-85312-924-X. £9.50.*

Science and Technology in World Development. By ROBIN CLARKE. *Oxford University Press: 1985. Pp.216. Hbk ISBN 0-19-219195-0; pbk ISBN 0-19-289176-6. Hbk £12.50; pbk £4.95.*

Solid State Chemical Sensors. JIŘÍ JANATA and ROBERT J. HUBER (eds). *Academic: 1985. Pp.211. ISBN 0-12-380210-5. $49, £49.*

Solid State Protonic Conductors III-for Fuel Coals and Sensors. J.B. GOODENOUGH, J. JENSEN and A. POTIER (eds). *Odense University Press: 1985. Pp.284. ISBN 87-7492-517-2. $20.*

Spectral Techniques and Fault Detection. MARK G. KARPOVSKY (ed.). *Academic: 1985. Pp.608. Hbk ISBN 0-12-400060-6. $44.50, £39.00.*

Technology, Institutions and Government Policies. JEFFREY JAMES and SUSUMU WATANABE (eds). *Macmillan: 1985. Pp.265. Hbk ISBN 0-333-38562-4. £25.00.*

Computer Science

Computing for Biologists: An Introduction to BASIC Programming with Applications in the Life Sciences. By ALAN FIELDING. *Addison-Wesley: 1985. Pp.190. Pbk ISBN 0-201-14574-X. Pbk £8.95.*

Introduction to Computer Systems: A User-View. By BRIAN MOLINARI. *Cambridge University Press: 1985. Pp.274. ISBN 0-521-24962-7. Hbk £22.50, $39.50; pbk £7.95, $14.95.*

Microcomputers. By D.G.C. JONES. *Adam Hilger: 1985. Pp.64. Pbk ISBN 0-85274-770-5. Pbk £2.95.*

Environmental Sciences

Air Pollution by Photochemical Oxidants: Formation, Transport, Control and Effects on Plants. R. GUDERIAN (ed.). *Springer-Verlag: 1985. Pp.346. ISBN 3-540-13966-4/0-387-13966-4. DM 158.*

Black Carbon in the Environment: Properties and Distribution. By EDWARD D. GOLDBERG. *Wiley: 1985. Pp.198. ISBN 0-471-81979-4. Np.*

Chemosphere: Chemistry, Biology and Toxicology as Related to Environmental Problems. Vol. 14, No. 6/7. *Pergamon: 1985. Pp.989.2/yr. $250.*

Chlorinated Dioxins and Dibenzofurans in the Total Environment II. LAWRENCE H. KEITH, CHRISTOFFER CHOUDHARY (eds). *Ann Arbor Science: 1985. Pp.547. Hbk ISBN 250-40646-2. £65.00.*

Earth Sciences

Categorical Data Analysis for Geographers and Environmental Scientists. By NEIL WRIGLEY. *Longman: 1985. Pp.392. ISBN 0-582-30127-0. £45.*

Changes in Global Climate: A Study of the Effect of Radiation and Other Factors during the Present Century. By K. Ya KONDRAT'EV. *Balkema: 1985. Pp.288. ISBN 90-6191-442-6. $29.50, £22.*

Humic Substances in Soil, Sediment and Water. Geochemistry. Isolation, and Characterization. GEORGE R. AIKEN, DIANE M. McKNIGHT, ROBERT L. WERSHAW and PATRICK MacCARTHY (eds). *John Wiley: 1985. Pp.692. Hbk ISBN 0-471-88274-7. £61.35.*

Karst Geomorphology. By J.N. JENNINGS. *Basil Blackwell: 1985. Pp.293. Hbk ISBN 0-631-14031-X; pbk ISBN 0-631-14032-8. Hbk £27.50; pbk £9.50.*

Mastodon-bearing Springs and Late Quaternary Geochronology of the Lower Pomme de Terre Valley, Missouri. By C. VANCE HAYNES Jr. *The Geological Society of America/Special Paper 204: 1985. Pp.35. Pbk ISBN 0-8137-2204-7. $10.00.*

Minerals Resources and Engineering Geology. AKIRA SASAKI, SHUNSO ISHIHARA and YOTARO SEKI (eds). *Wiley: 1985. Pp.299. ISBN 0-471-10536-8. £27.95.*

The Polar Cusp. JAN A. HOLTET and ALVENGELAND (eds). *Reidiel: 1985. Pp.422. ISBN 90-2771923-3. Dfl.160, $55, £40.75.*

Preferred Orientation in Deformed Metals and Rocks: An Introduction to Modern Texture Analysis. HANS–RUDOLF WENK (ed.). *Academic: 1985. Pp.610. ISBN 0-12-744020-8. $59.50, £59.50.*

The Puzzle of the Plates: Spilhaus Repeating World Map. (Educational Jigsaw.) Created by ATHELSTAN SPILHAUS. *American Geophysical Union: 1985. Np.*

Quaternary Environments: Eastern Canadian Arctic, Baffin Bay and Western Greenland. J.T. ANDREWS (ed.). *George Allen & Unwin: 1985. Pp.774. ISBN 0-04-551094-6. £50, $75.*

Soil Reclamation Processes: Microbiological Analyses and Applications. ROBERT L. TATE III and DONALD A. KLEIN (eds). *Marcel Dekker: 1985. Pp.368. ISBN 0-8247-7286-5. $71.25.*

Syngenesis and Epigenesis in the Formation of Mineral Deposits. A. WAUSCHKUHN, C. KLUTH and R.A. ZIMMERMANN (eds). *Springer-Verlag: 1985. Pp.653. ISBN 3-540-13845-5 0-387-13845-5. DM 175.*

Biological Sciences

Advances in Prostaglandin, Thromboxane, and Leukotriene Research: Platelets, Prostaglandins and the Cardiovascular System. GIAN G. NERI SERNERI *et al.* (eds). *Raven: 1985. Pp.393 ISBN 0-88167-062-6. $35.*

AIDS-Associated Syndromes. S. GUPTA (ed.). *Plenum: 1985. Pp.181. Hbk ISBN 0-306-42016-3 Np*

Alternative Immunoassays. W.P. COLLINS (ed.). *Wiley: 1985. Pp.244. ISBN 0-471-90669-7. £28.*

Behavioral Evolution and Integrative Levels. GARY GREENBERG and ETHEL TOBACH (eds). *Lawrence Erlbaum: 1984. Pp.307. ISBN 0-89859-363-8. £28.75.*

Biochemistry of Plant Cell Walls. C.T. BRETT and J.R. HILLMAN (eds). *Cambridge University Press. 1985. Pp.312. ISBN 0-521-30487-3. £19.50.*

Biology of the Nerve Growth Cone. STANLEY KATER and PAUL LETOURNEAU (eds). *Alan R. Liss: 1985. Pp.351. ISBN 0-8451-0242-7. £34.00*

Biology of Pteridophytes: Proceedings of the Symposium held at Edinburgh, Sept. 12-16 1983. A.F. DYER and C.N. PAGE (eds). *The Royal Society of Edinburgh: 1985. Pp.474. £17.*

Brain Imaging and Brain Function. LOUIS SOKOLOFF (ed.) *Raven: 1985. Pp.308 ISBN 0-88167-084-7. $70.50.*

Catecholamines as Hormone Regulators. NIRA BEN-JONATHAN, JANICE M. BAHR and RICHARD I. WEINER (eds). *Raven: 1985 Pp.396. ISBN 0-89004-607-7. $47.*

Color Atlas of Kidney Biopsy: Pathology of Glomerular Diseases. By W. ROTTER.*Alan R. Liss 1985. Pp.280. ISBN 0-8451-0239-7. £95.*

Computer-assisted Bacterial Systematics. M. GOODFELLOW, D. JONES and F.G. PRIEST (eds). *Academic: 1985. Pp.443. Hbk ISBN 0-12-289665-3. $75.00, £55.00.*

Current Primate Researches. M.L. ROONWAL S.M. MOHNOT and N.S. RATHORE (eds) *Department of Zoology, University of Jodhpur, Jodhpur-342001, India: 1984. Pp.626. Np.*

Developments in Ophthalmology, Vol. 12: Visual Field in Glaucoma. Cellular Proliferation. W STRAUB and B.P. GLOOR (eds). *Karger: 1985 Pp.134. ISBN 3-8055-4022-1. SwFr. 93, DM 111 $39.75.*

Diseases of Marine Animals. Vol. IV, Part 1 Introduction, Pisces. O. KINNE (ed.). *Biologische Anstalt Helgoland, Hamburg, Federal Republic of Germany: 1984. Pp.541. ISBN 3-98008183-4. Np.*

Ecosystem Theory for Biological Oceanography. ROBERT E. ULANOWICZ and TREVOR PLATT (eds). *Department of Fisheries and Oceans, Ottawa, Canada: 1985. Pp.260. Pbk ISBN 0-660-11900-5 (Canada) $14.95, (other countries) $17.95.*

The Endocrine System and the Environment. BRIAN K. FOLLET, SUSUMU ISHII and ASHA CHANDOLA (eds). *Springer-Verlag: 1985. Pp 329 ISBN 3-540-15101-X/0-387-15101-X. DM 118.*

Environmental Regulation of Microbial Metabolism. I.S. KULAEV, E.A. DAWES and D.W TEMPEST (eds). *Academic: 1985. Pp.515. ISBN 0-12-428580-5. $49, £38.*

The Epigenetic Nature of Early Chordate Development: Inductive Interaction and Competence. By P.D. NIEUWKOOP, A.G. JOHNEN and B ALBERS. *Cambridge University Press: 1985. Pp.373 Hbk ISBN 0-521-25107-9. Np.*

Experimental Approaches for the Study of Hemoglobin Switching. GEORGE STAMATOYANNOPOULOS and ARTHUR W. NIENHIUS (eds) *Alan R. Liss: 1085. Pp.514. Hbk ISBN 0-8451-5041-3 £59.00.*

Fish and Shellfish Pathology. ANTHONY E ELLIS (ed.). *Academic: 1985. Pp.412. Hbk ISBN 0-12-237490-8. $69.50, £53.50.*

Flowering Plants of the World. V.H. HEYWOOD (ed.). *Croom Helm: 1985. Pp.335. Hbk 0-7099-3778-4. Hbk £19.95.*

Fragile Sites on Human Chromosomes. By GRANT R. SUTHERLAND and FREDERICK HECHT. *Oxford University Press: 1985. Pp.280. ISBN 0-19-503542-9. £40.*

Genetics, 3rd Edn. By MONROE W. STRICKBERGER. *Macmillan, NY: 1985. Pp.842. Pbk ISBN 0-02-946740-3. Pbk £15.95.*

Global Ecology. CHARLES H. SOUTHWICK (ed.). *Blackwell Scientific: 1985. Pp.323. Pbk ISBN 0-87893-810-9. Pbk £14.80.*

Hematopoietic Stem Cell Physiology. EUGENE P. CRONKITE, NICHOLAS DAINIAK, RONALD P. McCAFFREY, JIRI PALEK and PETER J. QUESENBERRY (eds). *Alan R. Liss: 1985. Pp.489. ISBN 0-8451-5034-0. £64.00.*

Higher Plant Cell Respiration. R. DOUCE and D.A. DAY (eds). *Springer-Verlag: 1985. Pp.522. ISBN 3-540-13935-4/0-387-13935-4. DM 298.*

Hormones and Human Behaviour. By BERNARD T. DONOVAN. *Cambridge University Press: 1985. Pp.223. Hbk ISBN 0-521-25881-2. Np.*

How The Dinosaurs Became Extinct. By S.N.U. FERNANDO. *Merlin Books: 1985. Pp.47. ISBN 0-86303-196-X. £1.25.*

Immobilised Cells and Enzymes: A Practical Approach. J. WOODWARD (ed.). *IRL Press: 1985. Pp.177. Pbk ISBN 0-947946-21-7. Np.*

In Search of the Double Helix: Darwin, DNA and Beyond. By JOHN GRIBBIN. *Wildwood House: 1985. Pp.369. Hbk ISBN 0-7045-3077-5. £12.95.*

The Intelligent Universe: A New View of Creation and Evolution. By FRED HOYLE. *Michael Joseph: 1985. Pp.256. Hbk ISBN 0-7181-2298-4; pbk ISBN 0-7181-2613-0. £8.95.*

The Interphotoreceptor Matrix in Health and Disease. C. DAVID BRIDGES and ALICE J. ADLER (eds). *Alan R. Liss: 1985. Pp.287. Hbk ISBN 0-8451-5040-5. £37.00.*

Intracellular Protein Catabolism. EDWARD A. KHAIRALLAH, JUDITH S. BOND and JOHN W.C. BIRD (eds). *Alan R. Liss: 1985. Pp.702. ISBN 0-8451-5030-8. Np.*

Isolation and Identification of Micro-Organisms of Medical and Veterinary Importance. C.H. COLLINS and J.M. GRANGE (eds). *Academic: 1985. Pp.387. ISBN 0-12-181460-2. $55, £45.*

Jones's Animal Nursing, 4th Edn. D.R. LANE (ed.). *Permagon: 1985. Pp.706. ISBN 0-08-031983-1. $38, £19.50.*

The Lactoperoxidase System: Chemistry and Biological Significance. KENNETH M. PRUITT and JORMA O. TENOVUO (eds). *Marcel Dekker: 1985. Pp.272. ISBN 0-8247-7298-8. $66.*

Linear Models in Biology. Linear Systems Analysis with Biological Applications. By M. R. CULLEN. *Ellis Horwood: 1985. Pp.213. Pbk ISBN 0-85312-905-3. $10.50.*

Membrane Fluidity in Biology, Vol. 3. Disease Processes. RONALD C. ALOIA and JOAN M. BOGGS (eds). *Academic: 1985. Pp.316. Hbk ISBN 0-12-053003-1. $64.50, £56.00.*

Membrane Protein Biosynthesis and Turnover. P.A. KNAUF and J.S. COOK (eds). *Academic. 1985. Pp.531. ISBN 0-12-153324-7. $89, £89.*

Methods in Enzymology. Vol. 112: Drug and Enzyme Targeting. KENNETH J. WIDDER and RALPH GREEN (eds). *Academic: 1985. Pp.589. ISBN 0-12-182012-2. $69.*

Microencapsulation and Artificial Cells. T.M.S. CHANG (ed.). *Humana: 1985. Pp.320. ISBN 0-89603-073-3. $65.*

Applied Biological Sciences

Advances in Cancer Research, Volume 44. GEORGE KLEIN and SIDNEY WEINHOUSE (eds). *Academic:1985. Pp.355. ISBN 0-12-006644-0. $55.00, £48.00.*

Alcohol and the Brain: Chronic Effects. RALPH E. TARTER and DAVID H. VAN THIEL (eds). *Plenum:1985. Pp.349. Hbk ISBN 0-306-41998-X. Np.*

Aldehyde Adducts in Alcoholism. MICHAEL A. COLLINS (ed.). *Alan R. Liss:1985. Pp.230. ISBN 0-8451-5033-2. £35.*

Basic Mechanisms and Clinical Treatment of Tumor Metastasis. MOTOMICHI TORISU and TAKESHI YOSHIDA (eds). *Academic:1985. Pp.661. ISBN 0-12-695680-4. $59.50, £59.50.*

Biological Control in Agricultural IPM Systems. MARJORIE A. HOY and DONALD C. HERZOG (eds). *Academic:1985. Pp.589. Hbk ISBN 0-12-357030-1. $49.50, £43.50.*

Calcitonin 1984: Chemistry, Physiology, Pharmacology and Clinical Aspects. A. PECILE (ed.). *Elsevier Biomedical Press:1985. Pp.485. Hbk ISBN 0-444-80690-3. $92.50, Dfl.250.00*

Carcinogenesis: The Role of Chemicals and Radiation in the Etiology of Cancer. ELIEZER HUBERMAN and SUSAN H. BARR (eds). *Raven:1985. Pp.538. ISBN 0-88167-130-4. $76.*

Circulatory Shock: Basic and Clinical Implications. H.F. JANSSEN and C.D. BARNES (eds). *Academic: 1985. Pp.242. ISBN 0-12-380240-7. $39.00, £35.00.*

Contributions of Modern Biology to Medicine. U. BERTAZZONI, F.J. BOLLUM and M. GHIONE (eds). *Raven:1985. Pp.261. ISBN 0-88167-029-8.$40.50.*

Current Issues in Toxicology: The Use of Short-Term Tests for Mutagenicity and Carcinogenicity in Chemical Hazard Evaluation. H.C. GRICE (ed.) *Springer-Verlag:1984. Pp.197. Pbk ISBN 3-540-13696-7/0-387-13696-7. Pbk DM 52.*

Drug Fate and Metabolism. Methods and Techniques, Vol. 5. EDWARD R. GARRETT and JEAN L. HIRTZ. *Marcel Dekker, New York and Basel:1985. Pp.345. Hbk ISBN 0-8247-7423-X. $79.50 (US and Canada), $95.25 (other countries).*

Encyclopedia of Medical Radiology. F. HEUCK and E. SCHERER (eds). *Springer-Verlag:1985. Pp.843. ISBN 3-540-13155-8/0-387-13155-8. DM 880.*

Germfree Research: Microflora Control and its Application to the Biomedical Sciences. BERNARD S. WOSTMANN *et al.* (eds). *Alan R. Liss:1985. Pp.512. ISBN 0-8451-5031-6. £60.*

Hyperthermic Oncology 1984, 2 Vols. JENS OVERGAARD (ed.). *Taylor & Francis: 1984. Vol. 1 pp.870, ISBN 0-85066-273-7. Vol. 2 pp.385, ISBN 0-85066-281-8. Vol.1 £70; Vol. 2 £40.*

Immunity to Cancer. ARNOLD E. REIF and MALCOLM S. MITCHELL (eds). *Academic:1985. Pp.659. Hbk ISBN 0-12-586270-9. $43.00, £38.00.*

Interferon Alpha-2: Pre-clinical and Clinical Evaluation. DANIEL L. KISNER and J.F. SMYTH (eds). *Martinus Nijhoff:1985. Pp.111. ISBN 0-89838-701-9. Dfl. 84, $19.95, £18.95.*

***In Vivo* Perfusion and Release of Neuroactive Substances: Methods and Strategies.** ALEJANDRO BAYON and RENE DRUCKER-COLIN (eds). *Academic:1985. Pp.322. Hbk ISBN 0-12-083350-6. $62.50, £54.50.*

Magnesium Deficiency: Physiopathology and Treatment Implications. M.J. HALPERN and J. DURLACH (eds). *Karger:1985. Pp.248. ISBN 3-8055-3979-7. $79.75, £58.50.*

Manual of Drug Therapy. DAVID A. SCHEINBER and LABE SCHEINBERG (eds). *Raven.1985. Pp.400. ISBN 0-88167-074-X. $21.*

Manual of Radiographic Interpretation for General Practitioners. By P.E.S. PALMER *et al. World Health Organization:1984. Pp.216. Pbk ISBN 92-4-154177-6. SwFr. 23.*

Monitoring for Adverse Drug Reactions. S.R. WALKER and A. GOLDBERG (eds). *MTP Press:1985. Pp.152. ISBN 0-85200-876-7. £29.95.*

Monitoring Human Exposure to Carcinogenic and Mutagenic Agents. A. BERLIN, M. DRAPER, K. HEMMINKI and H. VAINIO (eds). *Oxford University Press:1985. Pp.457. Hbk ISBN 0-19-723056-3. £25.00.*

Monoclonal Antibodies in Cancer. STEWART SELL and RALPH REISFELD (eds). *Humana: 1985. Pp.448. ISBN 0-89603-068-7. D 74.50.*

Neuroendocrine Correlates of Stress. KENNETH W. McKERNS and VLADIMIR PANTIC (eds). *Plenum:1985. Pp.345. Hbk ISBN 0-306-42072-4. Np.*

Novel Biochemical, Pharmacological and Clinical Aspects of Cytidinediphosphocholine. V. ZAPPIA *et al.* (eds). *Elsevier:1985. Pp.406. ISBN 0-444-00967-1. $78.*

P-450 and Chemical Carcinogenesis. YUSAKU TAGASHIRA and TSUNEO OMURA (eds) *Japan Scientific Societies Press/Plenum:1985. Pp.175. ISBN 0-306-42123-2. Np.*

The Patient, Biological, Psychological, and Social Dimensions of Medical Practice, 2nd Edn. By HOYLE LEIGH and MORTON F. REISER. *Plenum: 1985. Pp.457. ISBN 0-306-41985-8. Np.*

Postoperative Pain: Understanding its Nature and How to Treat it. By JANE HOSKING and EDWARD WELCHEW. *Faber & Faber:1985. Pp.175. ISBN 0-571-13538-2. £4.95.*

Practical Fow Cytometry. By HOWARD M. SHAPIRO. *Alan R. Liss:1985. Pp.295. ISBN 0-8451-0243-5. £37.50.*

Prevention of Head Injuries in Skiing: Mechanisms, Experimental Study, and Prevention. By SOOYOUNG OH. *Karger:1985. Pp.164. Pbk ISBN 3-8055-3978-9. SwFr. 49, DM 59, $21.00, £15.40.*

Principles of Medical Therapy in Pregnancy. NORBERT GLEICHER (ed.). *Plenum:1985. Pp.1290. ISBN 0-306-41845-2. Np.*

Principles of Plant Biotechnology: An Introduction to Genetic Engineering in Plants. By S.H. MANTELL, J.A. MATTHEWS and R.A. MCKEE. *Blackwell Scientific:1985. Pp.269. Pbk ISBN 0-632-01215-3. Pbk £10.80.*

Progress in Medical Radiation Physics. COLIN G. ORTON (ed.) *Plenum:1985. Pp.254. ISBN 0-306-41789-8. Np.*

Western blotting kit for AIDS virus

The latest batch of new products includes a touch-sensitive video display from Zenith and from Bio-Rad a kit for analysis of the AIDS virus

- New from Enzo-Biochem is a ready-to-use nick-translation kit which includes all the necessary reagents and a detailed protocol for the biotinylation of DNA probes. A biotin-labelled nucleotide, Bio-II-dUTP, replaces TTP in the standard nick-translation reaction. Standard procedures for nick-translation are used and result in substitution of 20–70% of the available thymidine residues with biotinylated dUTP. The Enzo nick-translation kit produces stable biotinylated DNA probes and is recommended for dot blots, Southern blots and for *in situ* hybridization. Detection systems are also available from Enzo-Biochem for immediate visualization of the probe.

Bel-Art's fully transparent desiccator.

- Bel-Art airtight desiccator cabinets provide a dust and moisture free environment for the storage and protection of samples, chemicals, specimens or electronic components. These economical cabinets are injection-moulded in high impact polystyrene for full transparency, rigidity, and strength. They are easily stacked which saves valuable bench space and are also suitable for refrigerator applications.

- Accurate and convenient pH measurement of low ionic strength solutions is now possible with the introduction of two new ranges of high-definition pH indicator sticks by May & Baker Laboratory Products of Manchester. Specially designed for use in weak solutions and part of the Dosatest range of pH indicators, the three zone and single zone sticks each consist of indicator pads firmly bonded to a plastic support allowing extended immersion times without solution contamination. The entire pH range is covered by the three zone sticks, one stick covers pH 0.0 to 6.0, another pH 4.5 to 10.0 and finally pH 7.0 – 14.0. Each of the three zone sticks has three hydrophobically separated indicator pads which change colour when immersed in the solution. A simple comparision of the new colour for each zone to that of the reference scale gives the pH of the solution to within 0.5 pH units. For very high definition pH measurements, May & Baker produce a range of one-zone plastic sticks which together cover a pH range of 0.3 to 9.5. The single indicator zone records the solution pH to within 0.2 to 0.5 pH units.

- The ProtoBlot immunoscreening system allows the use of rabbit or mouse primary antibodies as probes to detect λgt11 recombinants containing DNA sequences of interest. The system consists of the highest quality affinity purified second antibody, alkaline phosphatase conjugates and the necessary colour development substrates. A positive control is included, consisting of a recombinant λgt11 ovalbumin clone and mouse monoclonal antibody. Also included is an *E. coli* extract for background reduction in cases where primary anisera contain cross-reacting nonspecific antibodies. ProtBlot is produced by Promega Biotec.

Acoustic waves actuate the Zenith touch-sensitive video screen.

- Zenith's acoustic touch system, a unique new system for interactive video displays, is based on surface acoustic wave (SAW) technology. SAWs are inaudible waves of high-frequency sound that are generated electrically and move across a solid surface like waves on water. In the acoustic touch system, two inexpensive piezoelectric elements mounted on the surface of a cathode ray tube or a glass overlay are electrically 'excited' and emit SAWs. Acoustic reflector strips along each edge of the tube face send the SAWs across the screen, creating an invisible matrix of touchpoints. When a finger interrupts the soundwaves, two more transducers sense it and a microprocessor locates the source of the break at a horizontal and vertical crosspoint. Because SAWs are affected by the amount of finger pressure applied, the Zenith system can also define pressure levels, a depth coordinate that makes acoustic touch the first 'three-dimensional' touch-screen system.

The HSC10000 bench-top centrifuge.

- Savant Instruments' new microcentrifuge, the HSC10000, is a table-top high-speed unit featuring accurate temperature control to ±1°C and speeds to 12,800 r.c.f. (10,000 r.p.m.) to rapidly bring down suspensions and colloids, precipitates and other flocs. An adjustable timer selects the interval for centrifugal action and a speed control permits settings in 20 increments of 500 r.p.m. The HSC10000 maintains any temperature between 5°C and 80°C within ±1°C and as many as 40 samples (0.4 ml microcentrifuge tubes) can be inserted into one of the nine available rotors for tubes from 0.4 ml to 15 ml. The heavy-duty Lexan cover is locked into place and the timer set. Centrifugal action separates the precipitate while the thermal system holds the temperature at the desired level for both product stability and repeatability. For the HSC10000, Savant offers a range of interconnecting tubing, hardware and accessories including a space-saving instrument cart.

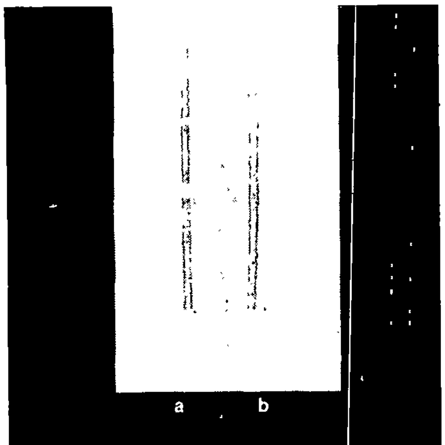
- A rapid and simple new radioimmunoassay kit for measuring rat atriopeptin III and other rat atriopeptins has been introduced by Upjohn Diagnostics. The simple four-step procedure provides results in a day and a half, and is available in a variety of formats for different levels of sensitivity. The assay antibody cross-reacts with atriopeptins I and II and rat alpha-atrial natriuretic peptide. *Reader Service No. 106.*



a) HTLV III/LAV Antibody Positive Human Serum.
b) HTLV III/LAV Antibody Negative Human Serum.

- Bio-Rad has introduced a range of products for AIDS Western blotting, a highly specific and sensitive technique for the serological analysis of HTLV-III/LAV virus and characterization of viral gene products. The enzyme-linked immunoelectrotransfer blot technique (EITB), developed at the Center for Disease Control, Atlanta, USA is a highly standardized method, utilizing high field intensity Western blotting after electrophoresis of viral proteins in SDS-PAGE. Two systems are available: one for rapid separation using miniature gels, the other provides high capacity, high resolution separations on standard gels. *Reader Service No. 107.*
- Laserspec, from Spectrolab, is a new, very high transmission tunable filter designed specifically for lasers. It interfaces directly with any laser and is suitable for beam widths of 0.5–5 mm diameter. Overall specifications are 80% transmission, 2Å bandwidth, 170 nm – 4 µm wavelength range. Being continously tunable, Laserspec can be used in laser spectroscopy, Raman, and wavelength rejection. *Reader Service No. 108.*

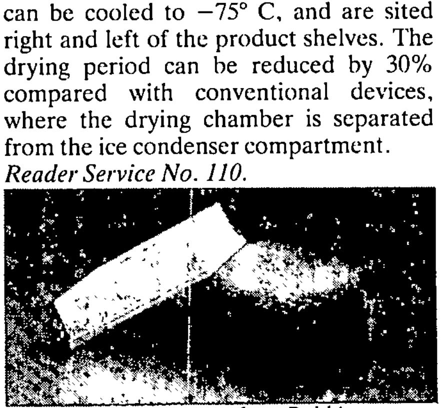
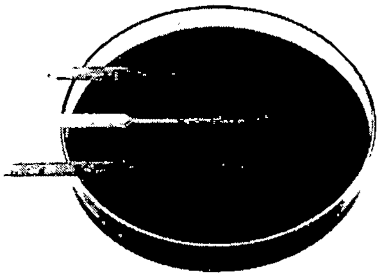
The Perkin-Elmer robot surrounded by its potential targets.

- The MasterLab robotics system from Perkin-Elmer provides the missing link in the entirely automated and integrated analytical laboratory: automatic sample preparation. The basic MasterLab system comprises a robot, a robot electronics module, a communications interface and an IBM PC. Each system can be designed to meet the automation requirements of a specific application or sample preparation procedure. Depending on the application, accessory modules such as mixers, dispensers or balances may be required to interface with the system. Several levels of automation are possible with the MasterLab system, for example: total automation which integrates robotic sample preparation with analysis and a laboratory information management system; sample preparation for subsequent transfer to instruments for analysis; specific applications, such as weighing samples, filtering, dispensing or handling dangerous substances. *Reader Service No. 109.*
- The latest freeze dryer from Martin Christ Gmbh is a unit in which the ice condenser is integrated with the drying chamber. During the drying process the water vapour is frozen, taking the shortest way over the ice condenser surfaces which can be cooled to −75° C, and are sited right and left of the product shelves. The drying period can be reduced by 30% compared with conventional devices, where the drying chamber is separated from the ice condenser compartment. *Reader Service No. 110.*



A rack of 125 pipette tips from Robbins.

- The disposable Titer-Pak II, from Robbins Scientific, consists of a box with telescoping cover and a sturdy, non-flex rack pre-loaded with 125 pipette tips. The tips are made of virgin polypropylene and can be used with Pipetman, Eppendorf and Excalibur pipettors up to 1,000 µl. This entire unit is disposable or can be autoclaved repeatedly without any distortion resulting. It is also available sterilized by cobalt irradiation. *Reader Service No. 111.*



Disposable 'Bioloops' come ready-sterilized.

- Elkay disposable Bioloop inoculating loops and needles are now available in a choice of four sterile packaging options: individually wrapped, 10-pack, 30-pack and 50-pack. Bioloops are pre-sterilized so there is no need for flaming prior to use, reducing risk of spreading pathogenic aerosols and saving time. Bioloops are available with a needle at one end and a 10 µl or 1 µl loop at the other. The third type has both a 10 µl and 1 µl loop. Each model is colour-coded for easy identification. *Reader Service No. 112.*
- New from Jasco Inc. is a research-grade spectrofluorometer, the Model FP-770. The instrument features *f*/2.5 optics permitting scanning from 200 to 850 nm (optional) at 1,000 nm per min. A computer data station for all user interaction provides functional keys for extreme ease of operation. The dedicated software program with its built-in self-diagnostic capability offers a 19-function range of computerized luminescence spectroscopy. The FP-770, a dual-beam with reference photomultiplier system corrected for light source fluctuation, has a wavelength accuracy of ±1.5 nm and repeatability of ±0.3 nm. *Reader Service No. 113.*

Damage is kept to a minimum by the Microfluidics continuous-flow cell disruption system.

- Controllable continuous-flow cell disruption with a minimum of damage to cell contents is achieved with the Microfluidics M-110 B. Self-contained, compact and light-weight, the M-110 B can be run on an open bench or placed in a laminar flow hood if required. The unit provides the option of processing dilute or concentrated cell suspensions as small as 10 ml through to 1 litre per minute pilot production runs. The M-110 B temperature-controlled models can operate down to −25° C, and full-scale models up to 20 gallons per minute are available.

Reader Service No. 114.

A program for the determination of dry weight and moisture content is available from Mettler.

- The dry weight and moisture content of samples taken from the drying oven can now be determined quickly and easily with a new program from Mettler LabWare—DRYING. It is stored on a microcassette and used as application-specific software in combination with a hand-held Epson HX-20 computer and a Mettler analytical or precision balance. DRYING stores the weight values and codes of up to 300 samples. After drying in the drying chamber, the samples are identified through their codes during back-weighing and the desired values are determined automatically. DRYING automatically records every every determination. In the case of a whole sample series, it even determines the mean value. The program uses a dialogue to guide the operator through the determination, and instructions appear on the 4-line computer display in English, French or German, or any desired fourth language.

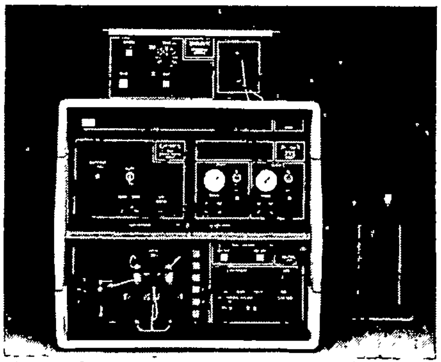
Reader Service No. 115.

- Two different designs are available in the Nordia fume cupboard range. The fume cupboards are fitted with toughened glass in a variety of timber and metal fabrications. The Nimrod range of aerodynamically designed compensated airflow fume cupboards, complying with the performance and safety requirements of DD80, is available in four widths. Standard features of the Nimrod range include a control panel incorporating a key-operated panel isolator with remote push button station for the extract fan motor, showing visual motor running/failed conditions. Other safety features include an optional audio-visual sash high and airflow failure alarms, a sash locking system and a heat sensor alarm/extinguisher. The economical Harrier fume cupboard range has been designed primarily for work involving lower levels of toxicity. Mason Nordia also provides and installs fume extraction systems, mechanical and electrical services and special gas installations.

Reader Service No. 116.

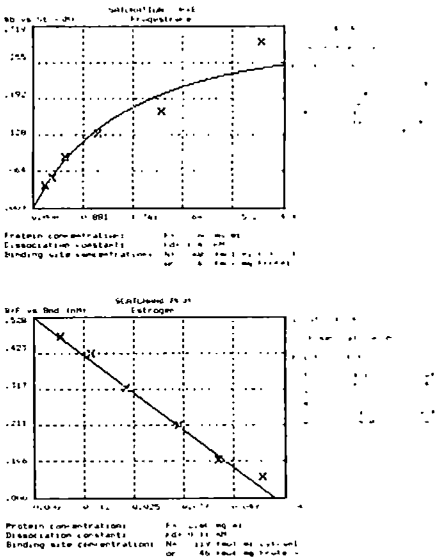
- Two new columns for the analysis of amino acids by ion chromatography are now available from Dionex. The HPIC-CS4 cation exchange and the HPIC-AS8 anion exchange columns provide complementary selectivities for the confirmation of amino acids, using advanced pellicular resin technology which allows high efficiency and high-speed separations without the limitations of traditional, totally porous ion exchange columns. The columns provide the specificity of classical ion exchange and the speed of pre-column derivatization. The Dionex ion chromatograph for amino acids is ideally suited for the analysis of amino acids in complex matrices with minimal sample pretreatment. The same system can perform state-of-the-art ion chromatography including the analysis of other ionic organic compounds and an extensive range of inorganic ions.

Reader Service No. 117.



A complete amino-acid chromatography system from Dionex.

- Packard Instrument Company has developed a new software program, COMBICEPT, for steroid receptor assays. Using a single assay, COMBICEPT provides simultaneous calculations of the oestrogen and progesterone receptor concentrations in tissue cytosols. Designed as part of Packard's Personal Computer Data Acquisition and Analysis System (PC-DAAS). COMBICEPT provides simultaneous dual-lable receptor assay calculations (oestrogen and progesterone), on-screen curve editing, multi-assay, multi-tissue data reduction, and on-line/off-line processing. Receptor data are stored on a floppy disk, and up to nine assay protocols can be stored. Each tissue is identified by a name, and the final results calculated using the individual protein concentrations. The software can be implemented on all present production models of Packard Tri-Carb and Auto-Gamma counters. Data for other systems can be processed manually.



Packard's latest steroid receptor assay program at work.

Reader Service No. 118.

- AMOR, from Spark of Holland is a new AMperometric detectOR for HPLC. This new electrochemical detector features a solid-state *in situ* reference electrode which is entirely maintenance-free. The working electrode is constructed so that the edge of the glassy carbon material is extraneous to the cell. The edge of the working electrode often causes noises and drift problems in EC detection. The cell is thermally insulated and electrically shielded. The cell volume may be varied by applying different (Teflon) spacers (0.4 – 1.0µl). Sensitivity range is from 0.1 nA to 1000 nA, and potential setting from −2 to +2V.

Reader Service No. 119.

- CelsiDot single level temperature sensitive labels are now available on rolls with 1,200 pieces of identical dots. There are 40 different temperature ratings available between 40°C (105°F) and 260°C (550°F). The white temperature sensitive indicating triangle turns permanently black when exposed above its rated temperature level. The self-adhesive labels can be applied to any clean, dry surface.

The brain drain is here again

from Richard Pearson

Much is made of the 'brain drain' of UK scientists to overseas posts, but little is known about the extent of the proble

THE brain drain is back in the news in the United Kingdom. The Civil Service is trying to plug the leakage of computer scientists to industry. The UK scientific community is worried about losses overseas. The universities complain about losses of academic lecturers to industry. There are some hopes that the Strategic Defense Initiative will reduce the brain drain from the United Kingdom. But in Ireland emigration remains an emotive subject with some educationalists seeking to play down talk about a brain drain. It is clear from these recent examples that the term 'brain drain' itself embraces a number of different flows and any assessment of its scale or impact depends on the perspective of the reporter.

Last year the Advisory Board for the Research Councils (ABRC) reported to the government its growing concern about the increasing losses of talented British scientists overseas. Its subsequent detailed enquiry, based on 40 leading research groups, showed that departments were gravely concerned about the losses not only of their most talented students and postdoctoral research workers but also of outstanding senior scientists. However, because the departments usually only employed small numbers of scientists they found it hard to present a statistical assessment of the flow or of the trends over time. They did, however, note a growing loss of senior chemists, materials scientists, biochemists and molecular biologists. The physicists and to a lesser extent the engineers reported far fewer problems. ABRC was able to identify 45 British senior scientists working overseas.

A more detailed study of biotechnology two years ago (*Nature* **309**, 654; 1984) revealed an estimated 250 UK nationals who had gone overseas in the previous decade, a total which excluded newly qualifying postgraduates[1]. The biotechnologists had gone to a wide range of countries and employing sectors. Typically leavers were aged 26–30 although one in three was aged over 30. The leavers went from industry, higher education and research institutes. The majority went however to jobs with commercial organizations. Nearly half went to the United States, with Switzerland and other European destinations for another one in three. In all, UK personnel went to 13 different countries and were working for over 65 different organizations. One new overseas biotechnology venture company had recruited over 16 UK nationals.

The reasons for losses overseas have been more related to improved job prospects and research opportunities overseas than salary, although the latter has usually come as a healthy bonus, and can be a major barrier for those thinking about returning. ABRC reported a growing frustration by senior scientists over the improved level of facilities, both recurrent support and equipment, available overseas, and the frustration over the difficulties in getting research funding approved in the United Kingdom. For younger scientists and those newly qualifying, then the flow overseas is seen as part of a more regular pattern of broadening their experience, usually in the United States, although growing numbers are thought to be going because of the lack of jobs in the United Kingdom. The recent restrictions on work permits in the United States may be restricting the scale of this potential outflow. The 'New Blood' scheme designed by the University Grants Committee (UGC) was thought to be helpful in the latter case, while additional UGC research funding is helpful with the former. The government has also cited the opportunities for 'star wars' research now available in the United Kingdom as another inducement to stem the flow. Two other factors aggravating the flow overseas are seen to be aggressive recruiting in the United Kingdom on the part of US universities and industry, and the greater receptiveness of US industry to novel and untried ideas. Where British laboratories have world class facilities, as at the Science and Engineering Research Council Nuclear Structure Facility or the Cambridge Laboratory of Molecular Biology, then they seem able to attract staff back from overseas and losses are not a significant problem. However, growing concern is reported over the level of funding and the lowering of morale which can only encourage further losses in the future.

Losses overseas are, however, usually

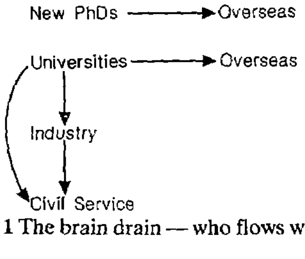

Fig. 1 The brain drain — who flows where?

only a very small part of mobility bet
sectors and its direct effect has been
to evaluate. Rather it has been seen
as a loss of potential. ABRC also re
growing concern about losses
academia to industry, particularl
chemists. However, one person's lo
another's gain and flows between se
within a country have not tended t
classified as a 'brain drain' in the pa
common international problem in tim
skill shortages is that there will nor

Discrimination is not cricket

A meeting in Paris on 17 January will decide whether to persist with the ban on South Africans at this year's archaeology congress in Southampton. The organizers should cut their losses and cancel.

WHAT connection can there be between the exclusion of people from South Africa from the planned congress of the International Union of Prehistoric and Protohistoric Sciences (IUPPS) at Southampton later in the year and the demand, a week ago, by the government of Bangladesh for a public denunciation of apartheid from a group of not particularly distinguished English cricketers? Or, for that matter, with some of the reactions there have been to the continued scandalous detention of Dr Andrei Sakharov in Gor'kii? These questions are not riddles left over from the holiday season, but should directly concern the members of the executive committee of IUPPS, which will be meeting next week in Paris to decide whether the ban on South African participation at the congress should stand.

What can happen? The best outcome would be some ingenious means by which the congress could go ahead without the academic community inflicting permanent damage on itself and the rest of us, but the chances of that are slim. The next best course would be to abandon the congress, acknowledging that the organizers are in an impossible position from which there is no honourable escape. To continue with the arrangements that have been made, or further to fudge the issue, will be intolerable.

The circumstances leading to the mess in prospect have been fully catalogued (see *Nature* **318**, 195; 1985). Briefly, responsibility for this year's congress was delegated by IUPPS to British archaeologists and anthropologists on the usual rota basis, but enthusiasm at Southampton for making the affair intellectually interesting and commercially successful must originally have seemed a plus. Planning fell to the British national committee, whose chairman, Professor John Evans, is also president of IUPPS, but most of the donkey work seems to have fallen to Professor Peter Ucko, secretary of the committee and also head of archaeology at the University of Southampton, the chief venue for the congress. By early last summer, the organizers had come under pressure to ban participants from South Africa. Pressure came from four different sources — students at Southampton (whose communal facilities were to provide space for a registration desk), the Association of University Teachers (AUT) which has a "national policy" that its members should not indulge in "academic relations" with South Africa, the British Anti-Apartheid Movement (which threatened to write to the embassies of anti-apartheid governments in London, and which may even have done so) and the Southampton City Council (which threatened to withdraw financial support and hospitality if South Africans were present at the congress). In September last year, the British committee capitulated, and South Africans were told they would not be eligible. There have been ructions ever since.

Cricket

Superficially, what happened last week in Bangladesh is not very different. As the English "B" team was gathering at London airport, the government of Bangladesh discovered that the names of three members of the party appear on a list, maintained by the United Nations in New York, of sportsmen who have played games in South Africa. The government demanded that those concerned should denounce apartheid and promise never to go to South Africa again. The English cricket authorities, offended by the blackmail and fearful about the precedents that would be set, refused, and the tour of Bangladesh is cancelled. Cricket enthusiasts now fear that the games planned for West Indies in the summer of this year (to which the English would have to send an "AAA" team to stand any chance of winning) will similarly be wrecked.

Scholarship

If cricketers placed in an impossible position find it prudent to cancel planned events, why should not archaeologists do likewise? That is the obvious parallel, even if the reality is more complicated. Both cricket and scholarship have separately been offered as ingredients of the cultural cement that holds international society together, helping to provide hope that contemporary problems in international relations will one day be solved amicably, by reason. Although practitioners of both kinds are fond of saying that scholarship (or cricket) should be kept away from politics, their international doings unavoidably have political consequences, usually beneficial. The practical question, that cricketers and scholars must separately ask, is how best to conduct their international affairs so as not to compromise desirable objectives, among which the disappearance of the tragically wrongheaded policies of apartheid from South Africa must be one.

Circumstances matter. One reason why national sporting teams no longer go to South Africa is the fear that to do so would be read in South Africa as tacit approval for a distasteful system. Just how to balance that argument against the calculation that going will help to loosen the system is not easy, but the sportsmen are probably correct in the decision they have reached. In much the same spirit, it is unthinkable that one of the scientific unions would now arrange an international conference in Pretoria. By the same test, it would be wrong for a scholar to accept an invitation from the government of South Africa to embark on a lecture tour or for some other purpose that could be misrepresented. But it does not follow that South African scholars, as people, are no longer a part of the international community, or that they have nothing to contribute to its wellbeing. One of the ironies of the Southampton ban is that it will affect some of those who, by the accidents of palaeontology, have the most to contribute. To the extent that some of those affected are from the Universities of Witwatersrand and Cape Town, which have been bastions of liberality for the past three decades, the ban is also a cruel way of dealing with courageous people.

Mishandling

This is only part of the reason why IUPPS should next week overrule its British committee's decision on South Africa. No amount of agonizing by a group of archaeologists, anthropologists and ethnologists can make much difference to the course of events in South Africa, but the mishandling of the Southampton congress could do damage that will persist for longer than apartheid can. The invitations (in reality, they were advertisements) originally sent to South African scientists were addressed to them as individuals, which was right and proper. The organizers have larded their ban with varying expressions of regret that the course they have felt compelled to follow will interfere with the free flow of ideas in science (and also infringe the statutes of IUPPS). There is wide sympathy for the position in which they find themselves, having to choose between the application of a principle they espouse and their understandable wish not to see months of careful planning wasted, perhaps at substantial cost. But there is no basis on which a group of scholars can exclude from an otherwise public meeting people who are qualified to attend, but whose government is socially unjust. To be the first in the field is a dubious distinction.

This is where the case of Dr Sakharov is relevant. Sakharov was an outspoken critic of the Soviet system a decade ago. He has not been charged with criminal activities, but merely sent to live in isolation from his friends and colleagues. Senior members of the Soviet academy say that Sakharov has been dealt with leniently, given the sharpness of his criticisms, but to their credit they have not expelled him from the academy, which would remove both his salary and his present degree of protection from administrative harassment. Even so, the case of Sakharov, like those of many other Soviet citizens who have suffered harsh administrative and legal penalties, has clouded scientific collaboration between Western and Soviet institutions. Yet at no stage has it been seriously suggested in the West that Soviet scientists as such are not welcome in the international community. If anything, the decay of formal collaboration has intensified the sense of loss that Soviet colleagues are absent from meetings at which they would naturally be found. Mercifully, but inconsistently, Soviet scientists have not been banned from Southampton. So why pick on South Africans?

The organizers say they have no choice, but they are wrong. Those who arrange meetings are always free to cancel them. Far better to stomach the embarrassment of wasted advertising literature than to be the first to introduce the principle of discrimination on the grounds of nationality into the conduct of intellectual affairs. Unless something can be done to make this congress respectable, it will probably be a tarnished affair, not merely on account of the notoriety it has attracted but because of the numbers of people who are threatening to stay away in sympathy with the handful of South Africans who will be excluded. The executive committee of IUPPS should bite the bullet and appeal to other scientific unions for help with the money problems left over.

Meanwhile, others must worry about the damage already done. The reputation of British academic institutions will have been harmed by this general advertisement of the power of campus demagogues, students and, lamentably, teachers. Does this mean that South Africans will be banned from all future international meetings in Britain? Does AUT's famous national policy deliberately invite this consequence, or is it merely a licence for local initiative by sporadic vigilantes? In their own interests, British academics should insist that the position of their representative body is clarified. AUT rightly spends most of its energy on academic pay and conditions of service, but its annual conferences may also adopt resolutions on more general matters. AUT's policy on South Africa is badly thought out.

More generally, there are international forces to be reckoned with. Although the constitution of IUPPS itself is explicitly non-discriminatory, the union is affiliated to UNESCO, which adopted a policy of deliberate discrimination against South Africans four years ago. Does that make sense? There is a more sinister threat in the statement by one of the Southampton organizers that it is no longer possible to organize an international conference to which "third world" scientists are invited without discriminating against South Africans. That cannot be the whole truth (witness the attendance of several South African astronomers at last December's meeting of the International Astronomical Union in Delhi), but even if it were a part of the truth, it would be a bad business for us all. □

Chopper politics

The British government seems bent on making a muddle of its policy on helicopter manufacture.

WESTLAND, a small manufacturer of helicopters based in south-west England, has become the centre of a bewildering row between British cabinet ministers for all the wrong reasons, which between them should provide a salutary warning for high-technology industries dependent on defence departments for their survival. The troubles stem from the nature of the helicopter as a means of transport. Although it was once commonly supposed that such machines had a bright future as means of almost personal transport, experience has shown them to be an expensive means of getting about, uncompetitive with fixed-wing aircraft over distances much greater than 100 kilometres and with surface transport over shorter distances. The only civil markets for the machines that matter are tiny, and are confined to circumstances where other means of transport do not exist (as in the servicing of oil-rigs at sea) or where a few minutes saved on a journey time may command a high price. (There is still a market for helicopter journeys between New York's principal international airport and Manhattan.) Otherwise, the helicopter has become almost exclusively a military vehicle, a means of transport and a battle-station.

Westland has known this for some time. For the past year, it has been pleading with the British Ministry of Defence under Mr Michael Heseltine for extra projects on which to work, and has been refused. So, under pressure from its bankers, Westland has been seeking larger companies willing to mount what is called in the trade a "rescue". The US corporation United Technologies, which owns Sikorski, another helicopter manufacturer, in conjunction with Italian Fiat, was the first in the field. Mr Heseltine has since organized a bid from a European consortium of aircraft manufacturers which differs chiefly in the amount of employment it offers the labour force at Westland. Members of the British cabinet have fallen out among themselves because some (including the Prime Minister) rightly say that the company should decide on commercial ground which bid to accept, while Mr Heseltine (who is not alone) threatens that Westland will not again win European orders for helicopters unless it accepts the bid he has organized (which it is within the power of European governments to ensure).

The piquancy of the resulting row derives from its bearing on British domestic politics. What the participants have forgotten is that Westland's problems of a year ago were a sign that there were then more helicopter manufacturers than the world's defence ministries could employ. Nothing much seems to have changed since then. And nothing has happened to suggest that Westland's technical dependence on other manufacturers (Sikorski in particular) will have been replaced by technical adventurousness in an admittedly difficult field. Mr Heseltine's European bid smells too much of an attempt to keep in being a company that is otherwise not viable by means of a redistribution of helicopter work among European governments.

The lesson to be learned from this should in reality have been learned a long time ago. The prizes now go to those who make technically advanced products of high quality. In civilian markets, to be second or third best is to invite disaster, but in the military field, chauvinism can keep projects afloat for longer than logic would allow. The fate of Westland has become an issue largely because the British government has resolved to let economic logic apply more rigorously than will other European governments. Mr Heseltine's laudable ambition that European defence forces should have access to the best equipment could just as well be satisfied by letting Westland go to the highest bidder and, quite separately, planning with European governments a strategy for buying (not necessarily making) the next generation of military helicopters. That way, he would discover, British taxpayers would find themselves paying less. □

Japanese technology

First sale overseas of military equipment

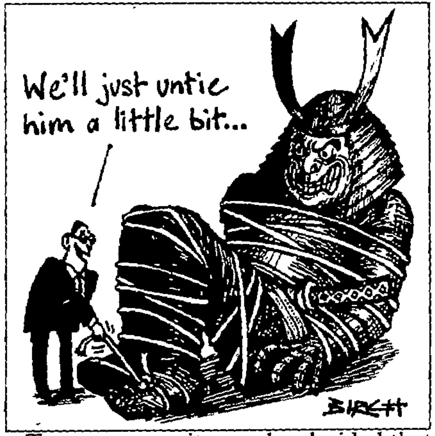
Tokyo

JUST before Japan's companies closed for the new year holiday, a small but potentially momentous technology deal was completed between the United States and Japan. The price of the deal is secret, but even if rumours that the US side moaned at having to shell out $40 million are correct, it will hardly add much to a mountainous trade deficit. The significance of the deal is that it is the first sale of military equipment by Japan to a foreign country since the Korean war.

The equipment sold to the United States consisted of anti-aircraft homing devices that, in contrast to the usual heat-seeking technology, guide missiles to their targets through visual tracking. The equipment employs charge-coupled devices similar to those used in the "seeing eye" sensors of autofocus video cameras. Japan has long been a leader in such research. The homing device was developed by the Technical Research and Development Institute, the government research body responsible for the development of weaponry for Japan's Self Defense Forces.

"Self-defence forces" is what they have to be called because Article 9 of the Japanese constitution specifically states that "land, sea and air forces as well as other war potential, will never be maintained. The right of belligerency of the state will not be recognised." Even self-defence forces are of doubtful constitutionality and must be as non-belligerent as possible. Defence is an extremely sensitive issue and a subject of continuous national controversy. The present government, which favours expansion, is hamstrung by the actions of Prime Minister Miki's government ten years ago. Back in 1976, it was decided that defence spending should be kept within 1 per cent of gross national product (GNP). (In contrast, the United Kingdom spends 5.6 per cent of GNP, a difference that has helped the development of Japan's non-military technology.)

This guideline, for it is nothing more, has now become an impenetrable barrier. Over the past year, Prime Minister Yasuhiro Nakasone has tried a hundred different roundabout ways of saying the limit would have to go, but without success. This year's defence budget is set at 0.993 per cent of GNP, provided the economy grows as well as is hoped. If UK accounting methods were used, Japan would already be spending 1.6 per cent of GNP. Over the years, some defence-related items have vanished from the defence budget; there was even once a suggestion that the troops' food was not strictly a defence item and could be taken out of the budget.



We'll just untie him a little bit...
BIRCH

Ten years ago, it was also decided that export of any kind of weapon or weapons component to any country, friendly or unfriendly, would be prohibited. This ruling has been enforced: when a company exported a metal component for a hand grenade trigger, the police took action. But that has not altogether prevented some bending of the rules. Japan, after all, manufactured the floating dock moored in Vladivostock for the massive Soviet aircraft carrier *Minsk*, on the grounds it was not necessarily for military use. More recently, under pressure from Washington, the United States alone has been excepted from restrictions. In November last year, the first Joint Military Technology Commission meeting was held to promote the transfer of military technology to the United States. Interest was apparently shown in high-speed gallium arsenide microchips and optical fibre communications equipment. Now the first technology sale has gone ahead.

The next big question for the Japanese government will be whether or not to participate in the US Strategic Defense Initiative (SDI). The decision by the United Kingdom to join the project is felt to have put the heat on Japan — it will have to say yes or no, rather than just trying to pretend that it had never been asked. Prime Minister Nakasone is known to be in favour of the project and the Foreign Minister has recently stated that the United States cannot be kept waiting too long for a decision. Both have repeatedly stressed that SDI is "defensive" and "non-nuclear". Government experts say participation would not be unconstitutional.

Business circles, on the other hand, cannot make up their minds whether they might be really missing out on some totally new technology if they do not join the project. But when all is said and done, it will still require an enormous push for Japan to join SDI. There is still only one issue that really unites the great mass of the people against the government that has been in power for 30 years — any hint of a move back towards militarism.

Alun Anderson

US science adviser

McTague fills Keyworth's shoes

Washington

JOHN McTague has been named acting director of the White House Office of Science and Technology Policy (OSTP), replacing George Keyworth II who resigned at the end of last year. McTague has been with OSTP since 1983 as deputy director.

McTague's temporary appointment has surprised many, as it was widely expected that Erich Bloch, director of the National Science Foundation, would be given the additional title of acting director of OSTP until a permanent replacement could be chosen. Indeed, that had been Keyworth's recommendation, but according to OSTP spokesman Maurice Roesch, acting director for defence programmes, "the idea was considered and rejected". McTague's interim appointment was a "collective decision" of the White House personnel office and OSTP.

McTague is a physical chemist. He was at the Institute of Geophysics and Planetary Physics at the University of California at Los Angeles from 1970 to 1982, after which he served as chairman of the National Synchrotron Light Source Department at Brookhaven National Laboratory until he joined OSTP.

McTague has enjoyed a good working relationship with Congress. Ezra Heitowit, staff director for the House of Representatives subcommittee on science, research and technology, describes him as "helpful and forthcoming with staff members".

A public supporter of the Strategic Defense Initiative (SDI) proposed by President Reagan, McTague is nevertheless unlikely to be as actively involved in promoting SDI as his predecessor.

The failure to name a permanent replacement for Keyworth will keep alive rumours about the possible demise of OSTP. But Roesch insists that the search for a permanent director is being carried out "as rapidly and expeditiously as possible", although he could suggest no timetable for when that permanent appointment could be expected.

Joseph Palca

British computing

Cooperative research spends up

The Alvey Programme, Britain's answer to the Japanese fifth-generation computing programme and the US integrated circuit programme, has now committed almost all of its £350 million budget. The money is being spent on "cooperative pre-competitive research in information technology" through the Department of Trade and Industry (DTI), the Ministry of Defence (MoD) and the Science and Engineering Research Council (SERC).

Alvey's director, Brian Oakley, says that a "very useful programme" has been mounted in the past two years, although he is not impressed by some of the government's financial restrictions; for example, no extra posts were provided for the programme, meaning that it is run on "the proverbial shoestring". Money for Alvey comes from funds that each department had already earmarked for other uses.

Alvey projects fall into five main categories: intelligent knowledge-based systems (23 approved projects); man-machine interface; very-large-scale integration (VLSI, exclusively focusing on silicon technology) and computer-aided design; software engineering (16 approved projects); and computer architecture. Of 550 proposals submitted to Alvey, 102 have been approved, 6 per cent of which are long-range speculative projects in universities. Each approved project includes an average of two or three industrial teams and one or two academic teams, ranging from two to eight partners per project.

Oakley admits that some mistakes have been made. One example is the Alvey requirement that, once a project has been technically approved, a collaborative agreement covering industrial property rights is required before money is paid. But the lack of advice or guidelines from Alvey has resulted in delays while arguments between partners were sorted out. "Quite inexcusable bureaucracy" resulted from the decision to divide up administrative duties — VLSI contracts to MoD and academic grants to SERC. The intention was to minimize the central administration team and to involve all participants in administrative decisions, but in fact bureaucratic differences and delays resulted. Oakley recommends that a non-governmental body should administer future collaborative schemes. Ten per cent of approved Alvey projects are also delayed by SERC's cash-flow problems, but Oakley foresees an end to these problems early in 1986.

Despite the problems, Alvey's annual report* provides evidence that a strong technology base is being provided in Britain by a directed collaboration between government, industry and academic research institutions. Alvey is halfway through its five-year life; the future of information technology research after this time is uncertain. Should Britain maintain its own attempt to compete with the United States and Japan or combine forces formally with ESPRIT, the European Strategic Programme of Research and Development in Information Technology?

Oakley is in no doubt that there is a strong need for both a national and an international programme. Geoffrey Pattie, minister for industry and information technology, hopes that a working group will be set up, with industry playing a "leading role" in deciding what is to be done.

Siberian river scheme

Russian party demands caution

A group of eminent Russian writers has called for the cancellation of the proposed southward diversion of the Siberian rivers. In a letter published last week by the daily *Sovetskaya Rossiya*, they say that the scheme "threatens serious consequences not only for future generations but also for those alive today". They condemn the project as an interference in "natural conditions that have built up over millions of years" and claim that the ecological, economic and social consequences have been insufficiently considered. Although opposition to the project has been voiced by Soviet environmentalists since the idea was revived in the mid-1970s, the writers' letter is unusually outspoken, attacking as "premature" the inclusion of the diversion scheme in the "Draft Guidelines" of the new five-year plan. Although the guidelines will formally remain open for public comment until the Party Congress next month, this remark questions the professional expertise of the high-level team responsible for this part of the plan, suggesting not so much a general relaxation of press censorship as the seriousness of concern over the diversion scheme. The appearance of such a letter, signed not by professional environmentalists, but by literary figures who in the West might be expected to show "green" tendencies, is itself significant.

The group includes Dmitrii Likhachev, perhaps the most eminent Soviet literary critic on the mediaeval period, and Leonid Leonov, whose literary career dates back to the early days of the Soviet Union. For several of them, this is not their first expression of hostility to the scheme — Vasilii Belov, one of the best known of the group, actually published a letter attacking the scheme in the Paris emigré newspaper *Russkaya Mysl'*, but it is their first public statement on the matter in the Soviet press.

Although they span three literary generations, the writers are all strongly committed to the traditions of old Russia. Some consider that the group constitutes a potentially significant political force, dubbed it the "Russian Party".

The fortunes of the group during the past few years have not been unclouded — during the June 1983 Plenum of the Central Committee, their views were attacked by Konstantin Chernenko, at the time propaganda secretary under General Secretary Yurii Andropov. Nevertheless, they have been largely responsible for the government's pledge that "monuments of Russian antiquity" should not be damaged. Such an assurance is significant in the context of Soviet hydroengineering, which before the Second World War submerged, among other places, the Dnieper rapids (analogous, for a Ukrainian, to drowning Runnymede or Harper's Ferry), and also the important archaeological site of Ithil, capital of the Khazars, the one gentile nation in the past 2,000 years to have converted to Judaism.

Vera Rich

Soviets ask for space

Academician Anatolii Aleksandrov, president of the Soviet Academy of Sciences, has called for a world space organization for international cooperation in the peaceful study and use of space. Such an organization, he said in an interview in *Pravda*, would ensure access for all states "on the basis of mutual advantage" to the data from meteorological, Earthscan and navigational satellites, and would be particularly beneficial to developing countries that cannot afford their own space programme. It would, furthermore, provide a framework for major cooperation in space research, and would also, by its very existence, "epitomize peaceful intentions in space".

The proposed organization, Aleksandrov suggested, would coordinate the activities of existing international bodies. He spoke glowingly of Soviet participation in the international KOSPAS–SARSAT experimental sea-rescue service jointly with the United States, Canada, France and Norway, and in the 10-nation Venus-Halley's comet programme.

Not all space cooperation, however runs auspiciously for the Soviet Union. A few weeks ago, there were reports of a major rebuff by the council of Inmarsat

Synthetic fuels

US Synfuels narrowly bites dust

Washington

THE Synthetic Fuels ("Synfuels") Corporation (SFC), willed into existence by Congress in 1980 with an annual spending power of $20,000 million, was legislated out of existence just before Christmas. But the controversial corporation's end was only narrowly prevented from turning into a $600 million spending spree.

SFC was formed when oil and natural gas prices were expected to continue to rise sharply, making the development of other sources of such fuels economically realistic. SFC's job was to support companies attempting to develop these alternatives. But reality turned out differently from expectations. Oil and natural gas prices did not rise precipitously, while large-scale projects for producing fuel from oil shale and natural gas from coal encountered technical problems for which expensive solutions were required.

In more than five years, only one of SFC's projects actually reached the point of producing energy on a commercially usable scale — the Cool Water coal gasification plant in California, which feeds into a combined cycle generator to produce electricity.

As its future came to seem less and less bright, members of Congress began to attack SFC as a rogue elephant, claiming that it was poorly managed and that its goals had in any case receded out of reach. Congress has also known that the Reagan administration has been sceptical of SFC since its inception towards the end of the Carter presidency. After fierce negotiations last year, by the end of the summer it was clear that SFC's days were numbered.

That prospect spelt disaster for two of SFC's projects, the Union shale plant at Parachute Creek in Colorado and the Seep Ridge oil shale project in Utah, both of which are still in need of SFC backing if they are ever to be viable. This dire prospect seems to have provoked the high drama in the days and hours before and after the congressional vote on 16 December.

Two interested senators, Jake Garn (Republican, Utah) and William Armstrong (Republican, Colorado) appear to have taken the initiative in asking the White House to allow the SFC board to meet and to provide the funds for the projects at risk before Congress had finally voted the corporation out of existence. If that had happened, the government would still have been liable for the commitments, in excess of $600 million.

Reports of what was afoot reached Capitol Hill together with the intelligence that the President's chief of staff, Donald T. Regan, has blessed the plan for a final meeting of the board, and even that the president might delay signing an abolition bill so as to give SFC a last chance to act.

The board of governors of SFC seems to have been in a difficult position. On the one hand, there were signals from the White House apparently authorizing new spending, but, on the other, clear indications that Congress wanted to call a halt to synthetic fuels development. In the end, the board decided not to act without written instructions. There appear to have followed several heated telephone conversations between members of the Congress and the White House, at the end of which the board was instructed to spend no more public money.

Ironically, the measure abolishing SFC was appended to a larger financial bill which was, in the end, defeated in the vote on 16 December. For a while, SFC was back in limbo, but supporters of SFC were unable to engineer a last-minute reprieve for the corporation, which was finally abolished when the larger financial measure was passed on 19 December. **Joseph Palca**

collaboration

the international programme for establishing a system of geostationary navigational satellites. According to the Soviet side, the list of rocket launchers initially accepted by Inmarsat includes the Soviet *Proton* rocket, which, the Soviet participants claim, is cheap and meets the programme's requirements. The United States has now opposed the use of the *Proton*, on the grounds that a launch from the Baikonur site would give the Soviet team the chance to acquaint themselves with the US equipment aboard the satellites, and remains unconvinced by Soviet assurances that the delivery of the rocket to the aunch-site, preparations for launching and the launch itself would be carried out n conditions that would exclude any "information leaks" about the on-board equipment.

The dispute over the abandonment of he *Proton*, which the Soviet side claims will mean a loss to Inmarsat of several million US dollars, was not mentioned by Aleksandrov. His vigorous urging of the benefits of pooling knowhow and economic assets in global space organization acquires, in the light of the Inmarsat disagreement, an additional topical note.

British biotechnology

Celltech within sight of profit

CELLTECH, Britain's budding biotechnology corporation, greeted the new year with an annual report showing a 27 per cent decrease in losses and a forecast of profitability by 1987. In the year ending 30 September 1985, Celltech's £3.8 million turnover more than doubled the previous year's. Chief executive Gerard Fairtlough reckons his company is the world leader in the bulk production of monoclonal antibodies, and is looking to Japanese and US markets, which account for about 85 per cent of Celltech's customers.

Although Celltech's cash balance fell from £9.8 million to £5.7 million during the year, Fairtlough says there is no present need to increase the company's equity base. Rather, Celltech is likely to rely on joint ventures of the kind that established Boots–Celltech Ltd in 1983 and Apcel Ltd in 1984. At its outset in 1980, Celltech gained impetus from an exclusive and widely-criticized agreement with the Medical Research Council (MRC) for first rights of refusal on all pertinent research. Although the five-year agreement was significantly qualified in 1983, Celltech's finance director Hugh Perrott says that the group still enjoys close collaboration with the council's laboratories.

Celltech's crowning accomplishment so far has been the development of a 1,000-litre fermentation tank, which churns out kilogram quantities of the antibodies that the US company Ortho Diagnostic Systems Inc. will market worldwide as blood group reagents.

Monoclonal antibody production occupies most of Celltech's culture products division, which also supplies antibodies for the purification of interferon and interleukin-2. Last year Celltech spent £2.4 million on expanding these facilities.

The health care division has agreed with the Japanese pharmaceutical firm Sankyo to develop calcitonin, potentially a treatment for osteoporosis and Paget's disease, and tissue plasminogen activator, which dissolves blood clots, for commercial availability. In the United States, Serono Laboratories Inc. has contracted Celltech to produce human growth hormone in mammalian cells and is already conducting clinical trials.

Fairtlough says he has suffered only one disappointment in his company's short history: chymosin, Celltech's first recombinant DNA product, had to be shelved because of patent difficulties and an over-estimation of the demand. Fairtlough contends that the dwindling (50 to 15 per cent) shareholdings of the British Technology Group (BTG), which provided the financial catalysis for Celltech's beginnings, does not reflect a lack of faith on BTG's part. He says that Celltech's shareholders are as satisfied as its customers.

Karen Wright

Bell Labs

From monopoly to competition

Murray Hill, New Jersey

REPORTS of the death of research at AT&T Bell Laboratories have been exaggerated. Since AT&T spun off seven regional telephone operating companies representing two-thirds of its assets at the start of 1984 in settlement of an anti-trust case, Bell Laboratories have indeed changed. But fears that the new slimmed-down AT&T would be unable or unwilling to support basic research in the style of the past have not materialized.

For 60 years, Bell Labs have been the world's foremost electronic research laboratories. Ian Ross, Bell Labs' president, argues that with a budget of $2,000 million and a staff of 19,000, the laboratories are of the scale expected of a company the size of AT&T (operating revenues in 1984: $33,000 million), and that basic research is now more important to AT&T than ever. What has changed is that the development staff, representing (as it did before 1984) some 90 per cent of the total, is now working more efficiently and with increased urgency to exploit usable research results to develop what he calls "killer technologies": technologies that will, like the transistor, lead to the demise of what went before. Basic research, he insists, remains untouched.

The corporate restructuring has, however, been far from painless. In the year following divestiture, Bell Labs lost 4,000 of their then 24,000 staff to AT&T information systems, which manufactures computers, and a further 4,000 to Bell Communications Research, the company set up to conduct research for the newly liberated local telephone companies. Some of the lost ground has since been regained, and Ross has used the opportunity to push Bell Labs in what he sees as the direction of AT&T's future: "we are", he says, "running like hell to change the technology mix".

The 1982 settlement that led to the break-up of AT&T also affirmed an earlier ruling of the Federal Communications Commission that allowed it to enter unregulated markets in information-handling. Ross's greatest hope for Bell Labs is that they will achieve a "fundamental solution to the problem of how to handle software", in which progress worldwide has been less spectacular than in hardware. Almost half of Bell Labs' employees are now producing software as their end-product, and Ross expects to see the proportion rise.

The Strategic Defense Initiative (SDI) is one area that would benefit from fundamental software advances and Ross is making bids on SDI contracts. Solid-state physics and chemistry, once at the forefront of Bell Labs' research, are by comparison now taking a back seat, while only a handful of researchers in economics and psychology remain to keep AT&T with a "window" in that field.

Not that Ross has abandoned physics; there are, he says, still two orders of magnitude of improvement in the circuit density of silicon integrated circuits to be achieved before fundamental constraints are reached, and three orders of magnitude of improvement in optical data transmission rates. Ross clearly intends that Bell Labs should maintain their pre-eminence in this area.

But for all Ross's enthusiasm, it is plain that the uncertainty of 1984 did cause a crisis of morale among Bell Labs' researchers. The losses to Bell Communications Research (Bellcore) and AT&T Information Systems were keenly felt; in Bell Labs' photonics research laboratory, for example, Bell Labs researchers work alongside Bellcore staff but are forbidden to share their research results. That irritation should soon be removed, when the Bellcore workers move into a new building now under construction. But AT&T's uncertain finances, which have caused large lay-offs in some manufacturing divisions, have led to what Ross calls a "salary structure freeze" across the company, including Bell Labs, meaning that salary increases are not awarded automatically. Ross says the "expectation" is that salaries "will be unfrozen" before long.

Many researchers, however, go to work at Bell Labs in part because of their reputation for having an easy collegiate atmosphere with the freedom to pursue academic interests. The introduction of symbols of corporate formality such as security checks for visitors and identification badges for staff therefore caused much resentment, and some took the changes as a cue to leave, most to go to universities.

One who did leave Bell Labs, Terry Miller, went to become professor of chemistry at Ohio State University; he says his decision was the result of a tempting offer and uncertainty about the climate for research at Bell Labs, but he remains in contact with former colleagues and does not now hesitate to recommend a research career there to inquiring students.

Not all divisions seem to have experienced attrition. Kumar Patel, executive director of research for physics and academic affairs, noted no change, but said the changed circumstances of AT&T meant that he had to "do more explaining" to hire promising researchers. But Patel's division has not been untouched by the changes to AT&T. Physicists in the division have shown the possibility of building a positron microscope, which would be an analytical tool with unique properties. "In the old environment, we would have done nothing about it", said Patel. Now, development staff are watching progress closely, and within two years a business decision will be taken on whether the positron microscope should be the target of a major Bell Labs development effort.

Arno Penzias, Bell Labs' vice president for research, is clearly stung by suggestions that AT&T's new competitive spirit will mean an end to the sort of unfettered basic research that led, for example, to his Nobel-prize-winning discovery of the cosmic microwave background radiation. Penzias defiantly points out that astrophysicists still work at Bell Labs, the justification being that the tools of their research may have applications to AT&T's technological base. High-energy physicists, by the same logic, are not employed. And Penzias insists that basic research staff, who now number about 1,000 ("crudely where it's been for a long time") are still encouraged to pursue long-term projects that might bring benefits in five to 20 years rather than more short-term gains. Researchers realize that they are protected as far as possible from the effects of fluctuating budgets, and most feel the worst of the crisis is over.

Penzias says that long-term strategic research at Bell Labs has always been important because, even before divestiture and despite the appearance of monopoly, AT&T always faced pressure to be competitive on prices. (Penzias cites AT&T's response to the establishment of COMSAT, which was to develop optical transmissions.) The change represented by divestiture for Bell Labs is merely in the way it benefits from successful research; before, it was mainly through cross-licensing agreements (the old AT&T was forbidden from benefiting directly from spin-off from its research), while now "one can envisage a script where AT&T cannot afford to pay its dividend". The effect is that research has "moved from being an important part of AT&T's prospects to a vital part".

Laboratory managers have been told to work harder to identify promising research breakthroughs at an early stage in order to alert promising development workers; while the development division has been totally reorganized into product line groupings that correspond to the activities of AT&T's other subsidiaries. Before divestiture, a researcher who found a result of possible interest would "write a memo, throw it over a wall and wait fo someone to answer", according to Davi Lang, head of semiconductor and electronics research: "Now they answer the telephones".

Penzias says the salary scheme for basi researchers at Bell Labs continues to encourage excellence in research, which i assessed and closely monitored by laboratory managers. (Efforts by researchers to ensure that their ideas are taken up by development staff are, however, now rewarded by salary bonuses, an innovation to reflect the changing times.) And Penzias believes in allowing researchers total freedom of inquiry. Mitchell Marcus, a linguistics and artificial intelligence researcher, agrees that he is given "more freedom than in a university". Alan Huang, who heads what may be the only corporate optical computing research department in the world, says he was "startled" shortly after divestiture to be told to take more risks in his research.

Huang's futuristic theorems on pattern recognition algorithms that might one day form the basic logical operations in optical computers are clearly exceptional, but his upbeat assessment of the post-divestiture working environment at Bell Labs is shared by many others. However, there is a niggle: Bell Labs have made a decision to be more careful about the information they will allow researchers to publish.

The irritation arises because recognition by peers is an important form of feedback, not entirely compensated for by the knowledge that permission to publish is being denied because of the possible importance to AT&T of the results being reported. Ross says he favours publishing more, but with "more on what we've done and less on how we did it". Fewer than one per cent of the 4,000 papers submitted for publication clearance each year are turned back for revision, but it seems to be accepted that irritation over this has increased: Ross says he is watching the subject "closely". Penzias cites the case of Narendra Karmarkar's celebrated algorithm in linear programming, now being used by AT&T for designing Pacific basin communication networks, as an example of the successful and judicious application of the policy: although Karmarkar's particular implementation of the algorithm remains proprietary, enough details were released for publication for Karmarkar to receive public recognition and win academic prizes.

Ross opposed divestiture at the time the question was being examined in court, and says he still believes the decision was a mistake. But it has allowed — or obliged — Bell Labs to be more responsive to technical developments. Ross complains that Bell Labs' most famous invention, the transistor, was brought into every home in transistor radios by other companies while AT&T spent 20 years in developing a version reliable enough for use in its only permitted application: telephone switching equiment. When the next "transistor" is invented, Ross says, "we can take it wherever we want". And, perhaps with good reason, he seems to have no doubt that there will be a next time.

Tim Beardsley

Israeli–Egyptian cooperation

Minor relic of Camp David

Rehovot

THE grandiose dreams of large-scale scientific cooperation between Egypt and Israel that flowered in the wake of Anwar Sadat's visit to Jerusalem in November 1977 and the peace treaty of March 1979 have not materialized. Nevertheless, despite intervening political storms, joint research projects in agriculture, mariculture and medicine have been quietly taking place.

As with the Camp David negotiations, US go-betweens have played an important role; the trilateral Cooperative Arid Lands Agriculture Research Programme (CALAR) was set up by researchers from Egypt, Israel and the United States at the University of San Diego, California, in June 1981, with financial support from the US Agency for International Development.

Although research programmes are developed and carried out independently in each participating country to suit specific conditions and needs, experience has shown that lessons learned in one are generally applicable in the other. This is certainly true of the exploitation for agricultural purposes of the abundant quantities of saline water in both Israel and Egypt.

One of the participating scientists, Professor Jehoshua Rudich of the Hebrew University's Faculty of Agriculture in Rehovot, points out that the Israeli practice until now has been to dilute saline water found in its desert regions (normally some five times as salty as ordinary irrigation water) with fresh water until it is only twice as saline. It is then used to irrigate salt-tolerant crops, notably cotton and melons.

More recently, within the framework of the CALAR programme, undiluted brackish water has been used to grow tomatoes (following the use of small quantities of sweet water to reach the flowering stage). The yields were slightly below normal, but the tomatoes were of high quality colour, acidity and flavour.

In parallel work in Egypt, Dr Adel S. El-Beltagy and his colleagues have shown, according to a recent CALAR report, that the local Edkawy variety of tomato is highly suitable for cultivation with saline water. They are, at the same time, producing water of various degrees of salinity and testing it with different methods of irrigation (drip, furrow), as well as studying how yields are affected by such factors as planting distances, windbreaks and fertilizers.

Another CALAR project in both countries involves the development of drought-resistant forage shrubs to feed sheep and goats. While the exploitation of brackish water is naturally emphasized, Dr Dov Pasternak of Israel's Ben-Gurion University, has set his sights on using water taken directly from the Mediterranean. His team has achieved encouraging results with approximately 50 plant species, most of them from the parched interior of Australia.

The Egyptians, meanwhile, have achieved significant progress in cross-breeding the Barki goat, a hardy native of their desert regions but a low producer of milk, with the high-producing Damascus goat.

A third sphere under investigation is the cultivation of crops that can be used as industrial raw materials. Successful results have been achieved in the deserts of both countries with jojoba, guayule and buffalo gourd.

Although political factors have kept cooperation out of the headlines, it has been reflected in more than a dozen joint Israeli-Egyptian presentations at international gatherings as well as joint papers in international scientific journals, mostly on the endemic parasitic afflictions leishmaniasis and malaria.

Medical cooperation began, however, with the mosquito-borne viral disease called Rift Valley fever. Ordinarily confined to central and southern Africa, it has killed 598 people and thousands of animals in Egypt since 1978. Israeli experts, fearing a further spread of the disease, readily agreed to a suggestion by the United States of discussions with their Egyptian counterparts.

Israel's main contribution has been made by a team led by Professor Rachel Galun of the Hebrew University's Kuvin Centre for the Study of Infectious and Tropical Diseases, which carried out studies on the behaviour of the mosquitoes that transmit the virus to cattle, sheep and man. Her findings were almost certainly of use in helping Dr Sherif El-Said of Ain Shams University and his colleagues in their successful efforts first to monitor and then to stamp out Rift Valley fever in Egypt.

Hebrew University researchers also worked together with Egyptian doctors and scientists after an outbreak of visceral leishmaniasis in Egypt. On that occasion, efforts in Jerusalem centred on the detection of antileishmanial antibodies by use of a new method that was developed there.

"Like all good cooperation", Professor Galun explains, "that between the Egyptians and ourselves has been based on mutual self-interest. For we both realize that infectious diseases and the vectors that carry them do not respect national boundaries."

Nechemia Meyers

Comecon technology

Plans laid for collaboration

THE Soviet bloc seems on the brink of novel schemes for technical collaboration. The Comecon economic summit in Moscow last month outlined five key areas of cooperation in its "Comprehensive programme" for collaboration among member countries "up to the year 2000". The five priorities, electronics, automation, nuclear power, new materials and biotechnology, hold no surprises — they were already earmarked for "integrated" cooperation at a previous summit in June 1984. More interesting, however, are the measures proposed for implementing cooperation, and the suggestion that the new programme could be the basis for cooperation outside Comecon itself.

The programme notes that the member countries have decided to translate the priorities "immediately" into specific agreements and contracts, embracing all stages of the "science/technology/production/market" process. The programme provides for direct relationships between scientific organizations and production enterprises in the member countries. Such relationships have until now usually been channelled through high-level organizations situated in the capitals of the countries concerned. This organizational development may fit in with the interest expressed by some Comecon countries in technical collaboration with West European governments. Direct relations of the kind now proposed would thus facilitate possible cooperation between the "comprehensive programme" and the West European Eureka programme, in which companies rather than governments will be the principal actors.

Comecon interest in Eureka has not been great, and the Czechoslovak party daily *Rude Pravo* has been downright hostile, alleging that Eureka and the US Strategic Defense Initiative (SDI) are closely linked, and that many companies likely to be involved in Eureka have already been contacted by the Pentagon, and will work simultaneously for both projects.

The one Comecon country to show real interest in a possible link-up with Eureka is East Germany, an interest that dates back to the visit of French Prime Minister Laurent Fabius to East Germany in June 1985. Perhaps significantly, the main Western interest in such cooperation seems to be coming from West Germany. Last month, Rudi Arndt, chairman of the socialist group in the European Parliament and himself a member of the West German Socialist Party (SPD), told a Moscow press conference that the delegation he had brought to Moscow might "smoothe the way for a formal agreement between the EEC and Comecon", and noted that the prospects for cooperation between the "comprehensive programme" and Eureka were "good".

The Soviet response to Eureka has so far been noncommittal. A Moscow television press conference after the Comecon summit noted that "there are a number of spheres of research and development of new technologies which are to be found in our programme and in the Eureka programme", but pointed out that the decisions leading to the Comecon programme were taken in June 1984, "at a time when no one had yet heard of Eureka".

Such an emphasis on the priority of the comprehensive programme is not, however, without its risks. President Ceaucescu of Romania has already criticized the programme, suggesting that the planners should first have implemented what they undertook to do in June 1984.

What Ceaucescu was referring to is not entirely clear, but he may well have meant the much publicized decision in 1984 to raise the economies and technological bases of the "less developed" Comecon countries (Mongolia, Cuba and Vietnam), to the level of the rest; the comprehensive programme says nothing specifically about these countries although the benefits they might expect were mentioned at the press conference afterwards. **Vera Rich**

West German space

Ministers at odds about Hermes

Bonn

THE federal ministers for research and foreign affairs are sharply in conflict over the proposal that West Germany should participate in the French plan to develop a space shuttle called Hermes. Heinz Riesenhuber, the Christian Democrat (CDU) Minister for Research and Technology, has set his face against collaboration in the project, saying that this could not be justified within the framework of his ministry's strategy for research and development. But the Free Democrat (FDP) foreign minister, Hans-Dietrich Genscher, is keen that West Germany should collaborate in the French project for the sake of Franco-German relations.

Riesenhuber's objections to collaboration have their root in budgetary problems. The minister says that German collaboration could not be financed out of the research budget as it stands, and that if West Germany is to take part in the Hermes project, the federal government will have to allocate extra funds for the work. This position is consistent with the decision of the federal cabinet a year ago that it would support no further large research projects until the 1990s.

Riesenhuber also argues, in further support of his unwillingness to participate in Hermes, that it would be senseless to invest in an "outdated technology", implying that Hermes is a copy of the US shuttle system. He compares the Hermes concept unfavourably with other schemes for the development of reusable space vehicles, such as the British Aerospace HOTOL concept. There is also, in Riesenhuber's mind, anxiety that the French project assumes continued use of the launching site at Kourou, in French Guiana, despite the "explosiveness" of the political climate there.

The dispute between the ministers appears to spring from the decision at the most recent meeting between the federal Chancellor, Helmut Kohl (CDU), and the President of France, François Mitterrand, that the two governments should sponsor a joint study project aimed at turning Hermes into a practical machine.

Riesenhuber's coolness on Hermes conflicts with the technical opinion given to him some months ago by the German Air and Space Research Institute (DFVLR), which recommended participation. But the minister points out that the DFVLR report drew attention to several technical defects of the French proposal such as the inability of the new Ariane V rocket system to compete economically with the new US shuttle-based technology and the intended polar orbit of Hermes, which would be incompatible with the orbits of the US space stations. The French plan would also require new emergency landing sites and data transmission networks. But Riesenhuber may have been chiefly influenced by the consideration that West German hopes to influence the development of an independent European space technology would be undermined if the funds were to be paid directly to the French.

The DFVLR proposals for a new West German initiative in advanced space technology are ambitious. The institute recommended spending about DM600 million a year on a three-cornered programme including both Hermes and the proposed European space vehicle "Columbus", intended as an adjunct to the proposed US space station.

Riesenhuber says that his research budget cannot cover costs on this scale, and is urging that any programme of this kind sponsored by the federal government should be partly financed by industrial sources, perhaps to the tune of 20 or 30 per cent. Riesenhuber points out that many of the proposed experiments could be of industrial value to German industry.

Jürgen Neffe

Sakharov's scientific legacy

Sir—Erast B. Gliner is right to say that Sakharov's contribution to science[1] should be emphasized in the campaign to end his exile and to save his life. However, Gliner's statement that Sakharov "is not considered as a head of some scientific school inside of the Soviet Union or abroad" is not entirely correct. Sakharov's pioneering work on the problem of a controlled thermonuclear reaction, which began the well known tokamak project, was the main reason for his election as a full member of the Academy of Sciences of the USSR in 1953, together with his co-author Igor Tamm. More than 20 years later, Sakharov was elected as a member of the US National Academy of Sciences for similar reasons. In a brief autobiography[2] published in 1974, Sakharov made a special point about two projects that he considered the most important of his contributions to nuclear physics:

> In the summer of 1950, almost simultaneously with the beginning of work on the thermonuclear weapon, I. E. Tamm and I began work on the problem of a controlled thermonuclear reaction; i.e., on the utilization of the nuclear energy of light elements for purposes of industrial power. In 1950 we formulated the idea of the magnetic thermo-isolation of high-temperature plasma, and completed estimates on the parameters for thermonuclear synthesis installations. This research, which became known abroad through a paper read by I. V. Kurchatov at Harwell in 1956 and through the materials of the First Geneva Conference on the Peaceful Use of Atomic Energy, was recognized as pioneering. In 1961 I proposed, for the same purposes, the heating of deuterium with a beam from a pulse laser. I mention these things here by way of explaining that my contributions were not limited to military problems.

In the Soviet Union, acknowledgment of Sakharov's work has been made only in publications from before 1968. Even though the tokamak project for which I. Tamm and A. Sakharov laid the foundations is continuing in the Soviet Union (the tenth, eleventh and twelfth tokamaks are now operating for research purposes), Sakharov's name has been omitted from the history of this field. Sakharov's role was last acknowledged in two official biographies of Igor Kurchatov published in 1967[3,4]. I. Golovin, a close colleague of Kurchatov (the head of the Soviet atomic project), recorded Kurchatov's reaction to Sakharov's theory in a very clear way: "Kurchatov was sitting in his study on New Year's Eve 1950 when he turned [to Golovin] and said: 'Sakharov has boosted us to tackle the second atomic problem of the twentieth century which is no less magnificent [than fission] — obtaining boundless energy by burning the waters of the ocean' "[4]. In some Western histories of Soviet science, the role of Sakharov in the tokamak project is fully acknowledged[5].

When asked about Sakharov's fate, some Soviet officials (including Anatoly Alexandrov, president of the Academy of Sciences of the USSR) normally answer that Sakharov is restricted to Gorky because he is in the possession of important military secrets and that this exile is made in strict observance of Soviet laws. Neither reason is correct. Sakharov was exiled to Gorky on the basis of an "individual" decree signed by the late President Leonid Brezhnev in 1980 as a reprisal for Sakharov's protest over the Soviet invasion of Afghanistan. There are no provisions in Soviet law for such a form of punishment, and the exile was imposed without any trial or decision of the court. Sakharov had had no access to classified information since 1968.

Now, when the new leadership clearly considers many aspects of Brezhnev's internal policy in a very unfavourable light, his legal actions may also be re-examined more carefully and critically. Gorbachev's intention to accelerate scientific and technological cooperation between East and West could not be served better than by restoration of full freedom to Sakharov.

Velikovsky

Sir—In his letter (*Nature* 10 October, p.470) criticizing the discussion of the Babylonian Venus observations in my review of Bauer's *Beyond Velikovsky*, Lynn E. Rose claims that he and Vaughan have worked to vindicate these data whereas Huber has rejected two-thirds of them.

The Babylonian texts in question were copied a millennium after the observations; there are so many variants between the copies as well as self-contradictions within individual tablets that at least 20 per cent of the data is suspect from the outset. As one of the most enthusiastic Velikovskians, Rose wishes to use these questionable data to prove that the Earth's orbit has changed dramatically in the past three millennia. Huber, as a scientist inclined to believe in the stability of the Earth's orbit, wishes instead to show that this corpus of material is statistically consistent with modern parameters, and even after throwing out the demonstrably bad sections of the text, over half of the 49 observations agree with modern values within the accuracy of the Babylonian observations.

C. Leroy Ellenberger, no longer a convinced Velikovskian, has pointed out to me that I might nevertheless have even better cited the uniformity of Greenland ice core Dye 3 as a way in which science could actually demonstrate that Velikovsky's scenario did not happen. This 2,000-metre sample is continuous and datable for the past 10,000 years and shows no dust or acid layers that would signal the sort of universal catastrophe predicted by Velikovsky.

Metric system

Sir—While endorsing all the comments made by your correspondent Alex Berezin (*Nature* **317**, 762; 1985), I hope that a mixture of different systems of units, including some nonmetric ones, will be retained, at least in the field of aviation. It is a major contribution to safety for a pilot to know that data quoted by radio in feet refer to altitude, while data quoted in metres refer to visibility, and that nautical miles are used to refer to distance along a route, from a radio beacon or airport, etc.

This system is standard throughout the world, the only exception being, characteristically, the United States, where statute miles are thrown in for measuring both visibility and distances, runways are measured in feet instead of metres and air pressure is quoted in inches (of mercury) instead of hectopascals.

If one overlooks this idiosyncrasy, the system works most satisfactorily and is very well suited to be used throughout international airspace, a space which is non-Euclidean, anisotropic and subject to changes of scaling factors (wind, air-pressure and so on) at any time.

Nuclear weapons

Sir—Edward Teller's letter (*Nature* **318**, 99; 1985) is accompanied by two graphs, one of relative numbers and the other of relative yields of US nuclear weapons. In both cases, the data presented end in 1980, before President Reagan's accelerated weapons programme, with which Dr Teller was closely associated and of which he should be in a position to present the consequences, both for numbers and yield. What are the figures for the past two years?

Pragmatism is not enough

SIR—It is a well-publicized fact that many species of organisms are in danger of extinction from human activities, especially in the humid tropics where massive deforestation threatens to exterminate countless forms not yet discovered by science. Fortunately, many individuals and organizations have risen to oppose the shortsighted economic and social behaviour that causes this problem — above all, the continued growth of human populations. Many arguments have been adduced for the importance of species preservation, including the actual or potential value of species as food or genetic resources, agents of biological control, components of healthy ecosystems and of our own life-support systems, or objects of aesthetic or intellectual interest. E. O. Wilson, in his recent book *Biophilia*, offers a more subtle argument: the innate affinity of man with other living things, and the fundamental connection between the value we place on them and the value we place on ourselves.

All these arguments are valid, and worth making at every opportunity. However, I suggest that we make a serious and possibly fatal tactical error when we rely solely on such justifications for species preservation. They are all based on the same flawed assumption: that the survival of a species is ultimately justified by its usefulness to man.

Take, for example, the popular argument that the humid tropics are vast untapped reservoirs of potentially valuable genetic diversity. This is true, and among the better reasons for preserving the rainforests. But what will happen to this justification if advances in genetic engineering in the next century make wild gene pools superfluous (or seemingly superfluous) for practical applications? The universal tendency of our technology, after all, is to replace natural products with synthetic ones, and to reduce our dependence on wild species of every sort.

When scientists try to oppose polluters, exploiters and developers solely with these kinds of pragmatic arguments about the value of species, ecosystems or gene pools to human well-being, we have already been manoeuvred into fighting on the ground they have chosen. Our pragmatic arguments for the long-term value of species will be weighed against their pragmatic arguments for the immediate needs of human beings. If an impartial judge rules that their arguments are more compelling and that a flood-control dam will objectively provide more tangible benefits to humanity than will an endangered species, to whom will scientists appeal?

If man's momentary need is allowed to decide the fate of other species, then in the long run the odds are stacked against them. Yet as scientists we owe our allegiance to objectivity and therefore to pragmatism. This, in my view, is why we cannot afford to speak only as scientists, or to let ourselves be limited by that label. We are scientists second and human beings first, and therefore must judge and act and justify our actions according to criteria that transcend science and pragmatism; namely, moral criteria.

If we are ultimately to preserve our biological inheritance, the only position we can take that is sufficiently strong — the only ground that is sufficiently high to be defended against the pragmatists, the economists, the politicians and the exploiters — is that we humans, as the *de facto* stewards of nature, are morally accountable for our stewardship. At the very least, we are accountable to posterity, and for such blunders as we have already committed with toxic and radioactive wastes, we may even live to be cursed by our own children. Those who acknowledge an authority above and beyond this world have still more reason to fear judgement. But if we pride ourselves on any claim to morality at all, whatever, its philosophical basis, that morality must lead is to use nature in a way that will preserve its diversity permanently intact.

This, admittedly, is a moral principle that is more implicit than explicit in many of the theologies and philosophies of the past. But just as there is progress in scientific understanding, there is also progress in moral philosophy and in what we are pleased to call "civilization". Little by little, the human race has grudgingly come to admit that certain things are simply wrong — such as murder, theft, slavery, torture, racism, genocide and even cruelty to animals. Though still committed, these are generally acknowledged, at least, to be crimes. Extermination of a species is also a crime. It is murder of a unique and irreplaceable evolutionary "individual"; it is theft at the expense of our own posterity; and it is a form of genocide as indefensible as any other.

These are the facts we must force mankind to admit, and ultimately to codify in enforceable international law; and there is no time to waste.

Bees in SE Asia

SIR—As people of, we believe, "some importance", we read with dismay your editorial on "Bees in South-East Asia" (*Nature* **317**, 190; 1985). Scientific thinking on this issue is clouded by political rhetoric on both sides. We wish to protes about a different matter — your judgement that "nobody of much importance seems to have taken the biological warfare scare seriously".

We take it seriously, as do some of our patients — the H'Mong people of Laos. I is our privilege to work at a hospital which cares for these surviving refugees. They know, perhaps better than any of us, jus how seriously to take it.

Atrocities are indeed hard to imagine To suggest that these people, who believe that biological warfare has been used against them, are "nobody of much importance", rings of past atrocities which also were denied.

We call on you to be more circumspect in conferring the mantle of importance on some people and not on others. And we caution that science is not well served by the assumption that the "important" people are more likely to be astute observers or logical thinkers.

Leprosy vaccine

SIR—Your report (*Nature* **317**, 665; 1985) about the proposed test of the World Health Organization (WHO) leprosy vaccine in India does not accurately represent the status of the method used to prepare the vaccine. Although this has not been formally published, the protocol is freely available from WHO and elsewhere and involves no proprietary or patented processes. Further, I have demonstrated the process in two separate laboratories in India, both of which have all the necessary apparatus and chemicals. Several visitors from India have also been shown how to purify *M. leprae* by the process. So it is not clear what technology needs to be transferred. The involvement of the company Wellcome in the matter is simply because materials for use in man must be prepared in licensed permises; there is no question of either development or exploitation of the process by Wellcome.

Your correspondent correctly comments that the main problem of indigenous production of the WHO-type vaccine is that the armadillo colony set up by the Indian Council for Medical Research failed to thrive. These are difficult animals to keep, but there is no restriction on advice and training on how to keep them.

There may indeed be instances where "multinationals" have restricted access to products by developing countries, but the leprosy vaccine is not such an instance.

Voyager 2 swings by Uranus

The US spacecraft launched towards Jupiter 8.5 years ago is about to encounter Uranus, a planet that has completed only two of its orbits since it was first discovered. The event could be exciting.

THIS time two weeks from now, on 24 January, the US space probe Voyager 2 will make its closest approach to the planet Uranus, providing many people with a reminder of a truth too easily forgotten, that for all its supposed familiarity, the Solar System is huge. The most striking sign of that is that Voyager 2 will have been on its way for more than eight years by the time it passes within 81,500 km of Uranus. Another is that Uranus, unlike both Jupiter and Saturn, is so far away (3×10^9 km) that it remains a bundle of conjectures that are unlikely to be resolved by a single spacecraft.

Nobody should be surprised. That it is just two centuries since Uranus was discovered gives the show away. In an orbit whose radius is 19.18 times greater than that of the Earth, Uranus intercepts only four per cent of the sunlight reaching the Earth even though its radius is 4.02 times as great. At that distance, the image is tiny (1.8 arc seconds across), small enough to fit inside the Great Red Spot on the surface of Jupiter.

The real surprise is what it was in 1781, that the discovery of Uranus should have fallen to German-born William Herschel, the professional oboe-player and musician who (like Handel) had followed the Hanoverians to Britain in search of a living, and who seems to have become an amateur astronomer by accident. The tale of how Herschel's gifted amateurism, which turned on his flair for making accurate mirrors from speculum metal, excited the enthusiasm of Georgian England was nicely told at the International Astronomical Union's symposium at Bath on the bicentenary. The way in which the irregularities in the orbit of Uranus led directly to the discovery of Neptune is another heroic tale. But for the rest, nobody is much wiser about Uranus than in Herschel's time.

Inference rather than direct observation remains the chief source of what little is known; none of the occasional reports of surface features on the planet is regarded seriously. Even the still startling intelligence that the spin axis of the planet is virtually parallel to the plane of its orbit derives most directly from the observation that the orbits of the five known satellites (the first two found by Herschel) lie in planes that are virtually perpendicular to the plane of the planet's orbit, although the measured oblateness (0.022, with an uncertainty of about 5 per cent), which varies with the phase of the planet at observation, fits in with the supposed spin axis. More recent attempts to learn something of the motion of the planet from Doppler measurements of atmospheric emission lines have helped only to pin down the period of rotation to about 15 hours (and few will be surprised if Voyager 2 recovers a different value).

This is why the next few weeks may bring more information about Uranus than the whole of the past two centuries. The hope is that the set of eleven experiments that gathered a rich harvest of information from the successive encounters with Jupiter (in 1980) and Saturn (in 1981) will still be functioning at Uranus (and at Neptune, which will be encountered on 24 August 1989, almost exactly twelve years after Voyager 2 was launched).

The visual observations may be even more telling on this occasion than at the previous encounters with outer planets. For if there are recognizable features on the surface of Uranus, it should at least be possible to learn directly something about the speed of revolution of the atmosphere of the planet (which is not necessarily that of the bulk). Indeed, the three cameras on Voyager 2 should be capable of yielding a resolution of better than 700 km for 700 hours before and after the encounter, which means that the daily newspapers may have splashed the first photographs of Uranus before this issue of *Nature* has appeared.

Another of the planned routes to a direct measurement of the speed of revolution may be a disappointment. If Uranus has a permanent magnetic field like that of the Earth, there will also be a magnetosphere that dominates the solar wind and, within that, a store of charged particles trapped in the magnetic field whose interaction with the atmosphere will give radio emissions varying with the rotation of the planet (if the magnetic and rotation axes are different). The first reports from what is called the Planetary Radio Astronomy Experiment suggest only meagre radio emission, at best. Perhaps there is no magnetic field worth speaking of. The next few days should tell.

This question has a bearing on the chemical constitution of Uranus and thus on current versions of the theory of how the planets were originally formed. Outwardly, Uranus and Neptune are similar. Uranus has 14.6 Earth masses, Neptune has 16.78. But the radii are oppositely related, at 4.02 and 3.89 Earth radii respectively. The difference of density may not be great, but it requires an explanation.

The standard assumption is that, even at these great distances from the Sun, planets will contain substantial quantities of the elements whose refractory oxides finish up as rocks on planets like the Earth. But Uranus and Neptune will have two other kinds of materials, those that form ices at the temperatures that reign (the atmosphere of Uranus, colder than that of Neptune, appears to be at a mere 65 K) but also materials that are still gaseous under those conditions, hydrogen and helium most significantly.

Given such a model, together with the mass and radius of the planet, it is possible to work out the relationship of pressure and density with depth beneath the surface. If the planet is spinning on an axis, it is also possible to relate the equatorial bulge and the aspherical components of the gravitational field to the speed of rotation, whence several attempts to calculate the rotational speed. (The shape of the gravitational field is inferred from, for example, the motion of the satellites or the shapes of the rings, of which, at Uranus, there are nine.) But here again, the data are not good enough to settle unambiguously the several persisting uncertainties. Here again, Voyager 2 should help enormously, not simply because its trajectory near Uranus is well designed for helping to pin down the gravitational field but because there will be direct measurements of the composition of the atmosphere

That raises several questions. The ratio of deuterium to hydrogen should be greater than on the Sun, but its measured value may be a guide to the temperature at which these planets formed. Why there is virtually no ammonia in the atmosphere of Uranus is another puzzle. (Methane is abundant.) The narrowness of the nine rings, and their apparent opacity, is another problem (but see this issue, p. 115) on which some light may be thrown by the very close approach to the innermost satellite Miranda expected for Voyager 2, a mere 15,000 kilometres. Whether there is an internal source of heat other than that of energy released by minor gravitational readjustments within an apparently stable planet may also be determined. The way things have turned out, the spacecraft is an instrument of which even Herschel would have been proud.

John Maddox

Ocean ecology

Light and ultraphytoplankton

from G. E. Fogg

H. Lohmann, studying filter mechanisms used by planktonic appendicularians to collect extremely fine particulate matter from sea water, pointed out the inadequacy of the conventional fine silk net for sampling plankton. He suggested that the small organisms which pass through the net could be important in the economy of the oceans because they might multiply much faster than the larger forms. The smallest of the phytoplankton, bacteria and tiny protozoa, are now grouped as picoplankton (diameter 0.2–2.0 μm) or ultraplankton (diameter less than 10 μm). The behaviour of these microorganisms is analysed in this issue (Glover, H.E., Keller, M.D. & Guillard, R.R.L. *Nature* **319**, 142; 1986) and was the subject of a recent NATO advanced study workshop. The conclusions support Lohmann's 75-year-old suggestion and mean that our ideas about ocean ecosystems will have to be revised.

Although it has often been noted that much of the photosynthetic activity of water samples is contained in the fraction that passes through the phytoplankton net, these minute organisms have remained largely unconsidered because they are so difficult to identify and count. Picoplankton only leaped into prominence when the value of the epifluorescence microscope for counting tiny coccoid cyanobacteria (blue-green algae) was realized (Johnson, P.W. & Sieburth, J. McN. *Limnol. Oceanogr.* **24**, 928; 1979 and Waterbury, J.B., Watson, S.W., Guillard, R.L. & Brand, L.E. *Nature* **277**, 293; 1979). Because they contain biliprotein pigments, these organisms are easily recognized by their strong and characteristic autofluorescence. Epifluorescence shows that they are abundant in most, if not all, the world's oceans, and the filter fraction in which they are collected contains most of the total photosynthetic capacity.

Physical considerations suggest that organisms of this size are peculiarly suited to planktonic life. Their sinking rates are negligible compared with the scale of the turbulence found in even the calmest seas. They have high surface/volume ratios which, combined with the steep diffusion gradients that are set up around very small sinks, allow them to take up nutrients at a high rate. Furthermore, a given amount of photosynthetic pigment dispersed in small cells absorbs light more effectively than an equivalent amount packaged in large cells. The strains examined in laboratory culture grow best at low light intensities of less than one fiftieth of full sunlight. Perhaps the only disadvantages of small size for a phytoplankter are the difficulties of moving into waters richer in nutrients or more favourably illuminated, and a greater vulnerability to predators.

Picoplanktonic cyanobacteria are generally found in concentrations of 10^4 cells per ml in inshore and offshore waters but are more evident in nutrient-poor offshore waters where larger phytoplankton, less able to use low concentrations of nutrients, are not successful. Although they are found throughout the water column in the euphotic zone, these cyanobacteria are concentrated at the bottom of the zone. This is not because they sediment out but is rather because they grow best in these conditions, using the low irradiance efficiently to support growth and benefiting from nutrients transported up from richer waters below. The oceanic picoplanktonic cyanobacteria contain large amounts of phycoerythrin, a pigment which seems admirably suited to absorb the blue-green light penetrating into deep water, but most of this pigment seems to be photosynthetically inactive, as demonstrated by its high fluorescence yield. Phycoerythrin may be more important as a nitrogen reserve than as an accessory photosynthetic pigment (Wyman, M., Gregory, R.P.F. & Carr, N.G. *Science* **230**, 818; 1985).

As well as cyanobacteria, there are eukaryotic ultraphytoplankton, detectable by the autofluorescence of their chlorophylls. These have so far scarcely been characterized and are difficult to grow in culture, but they are sometimes more abundant than the cyanobacteria in deep water and seem to grow best at even lower irradiances. Glover and her colleagues have now examined the photosynthetic performances and growth efficiencies of such forms at different irradiance levels and in different wavebands and find that the eukaryotes do better than the cyanobacteria in the dim blue-violet light that penetrates to the bottom of the euphotic zone in clear oceanic waters. Chlorophylls *b* or *c*, the major accessory pigments of these organisms, promote absorption in this region of the spectrum. In contrast, cyanobacteria grow best in green light. The larger eukaryotic phytoplankton have lower efficiencies at low irradiances than the ultraplanktonic species, probably as a result of the size effect discussed above.

It appears that eukaryotic ultraplankton, being adapted to low light intensities, can occupy a zone in which an ample nutrient supply is maintained by transport upwards from deeper water whereas the cyanobacteria need higher irradiances but can persist in waters which are sometimes depleted of combined nitrogen, and perhaps phosphorus, because of their high storage capacity. Further investigation of the physiology of these highly successful tiny organisms, together with increasing knowledge of the activities of the heterotrophic ultraplankton, will help to complete a picture of one component of an ecosystem that is probably responsible for most of the energy transformations and recycling of materials taking place in the oceans. □

Cell biology

Life without clathrin

from James E. Rothman

During receptor-mediated endocytosis, the process by which many macromolecules are taken up from the extracellular fluid into cells, receptors cluster in specialized regions of the cell surface, which invaginate to form coated vesicles. The coating is made of protein and the best characterized of the proteins is clathrin. It has always been assumed that the spontaneous assembly of clathrin molecules into a polygonal array on the surface of the budding vesicle is responsible for driving the budding process. This has also been seen as attractive paradigm for the mechanism of vesicular transport between intracellular compartments. But does clathrin play that role in intracellular transport? Do clathrin-coated vesicles mediate biosynthetic intercompartmental protein transport, such as the distribution of newly synthesized proteins from the endoplasmic reticulum via the Golgi stacks to plasma membranes, secretory granules and lysosomes? Three recent papers offer some new and surprising answers to these fundamental questions[1-3].

From immunofluoresence studies using antibodies to clathrin it has been clear that clathrin is localized both to the Golgi complex and to the plasma membrane, suggesting a role for clathrin in both biosynthetic and endocytic protein traffic. But an important extension of such studies by Griffiths *et al.*[1] and Orci *et al.*[2] has now greatly limited the steps in biosynthetic protein traffic that might be mediated by clathrin-coated vesicles and has led to the discovery of a new type of morphologically coated vesicle, which seems not to contain clathrin. Using colloidal gold-based immunocytochemistry combined with electron microscopy to localize clathrin antigens in the Golgi complex, both groups find that clathrin is mostly concentrated at the trans-most cisterna of the Golgi stack.

The Golgi stack is an asymmetrical structure comprizing a series of distinct compartments or cisternae. Proteins arrive from the endoplasmic reticulum at one end (the 'cis' face) of this stack, pass from one compartment to the next, and finally emerge from the last cisterna at the opposite ('trans') end. Thus, the restriction of clathrin-coated vesicles to the trans-most cisterna suggests that, at most, clathrin-coated membranes serve as carriers from this location to terminal destinations, such as the cell surface, secretory granules and lysosomes.

It is generally agreed that clathrin probably coats primary lysosomes and newly formed secretory granules in the cell. By contrast, a protein that is known to be destined for the plasma membrane (the vesicular stomatis virus-encoded G protein) could not be detected by Griffiths *et al.*[1] in the clathrin-coated buds forming from the trans-cisterna. The picture that seems to be emerging is that clathrin-coated vesicles are restricted to routes connecting the Golgi with some terminal destinations of biosynthetic traffic, but perhaps not the plasma membrane. Lysosomal enzymes and secretory proteins destined for storage granules may be selectively removed from the Golgi in clathrin-coated membranes. Perhaps the left-overs — consisting of cell-surface proteins and constitutive (unregulated) secretions — are transported to the plasma membrane by other types of vesicles, whose content may not be nearly so selective. Of course, the picture may be still more complicated, with polarized cells having multiple surface domains.

Given that clathrin is restricted to the Golgi exit point, how do transported proteins move from the endoplasmic reticulum to the Golgi, and from one cisterna to another across the stack? Another surprise described by Griffiths *et al.*[1] is that although there are morphologically coated vesicles or buds at all levels of the Golgi, they are not labelled by antibodies to clathrin. As the authors point out, the simplest explanation is that these coated structures are not made up of clathrin. The clear and exciting implication is that a new type of coated vesicle, whose coat protein is yet to be discovered, carries biosynthetic protein traffic up to the trans-most Golgi cisterna. A number of mysteries are created. Why is the same type of clathrin coat not used at all stages of biosynthetic protein transport? Are the new type of coated vesicles capable of selective protein transport, like clathrin-coated vesicles, or might they have quite different functions, perhaps even as bulk carriers? In this connection, note that the first station where a choice of destination must be made along the biosynthetic protein-transport pathway is probably in the trans-most cisterna of the Golgi stack, which is where clathrin is first found.

Clathrin-coated vesicles from chicken oocytes. × 125,000, 1% uranyl acetate stain. Photograph courtesy of B. Pearse.

Yet another surprise is that some cells can manage quite well without any clathrin at all. This sobering finding emerged when Payne and Schekman[3] deleted the single clathrin gene from yeast. Yeast has coated vesicles and its clathrin, like mammalian clathrin[4], is composed of three-legged 'triskelions' containing equimolar amounts of a heavy chain (190 kD in yeast) and a light chain (36 kD)[3]. Payne and Schekman prepared an antibody against the yeast heavy chain and used this to isolate the heavy-chain gene from a library of yeast DNA in a phage lambda expression vector. Using what are now standard methods in yeast genetics, they replaced the normal clathrin heavy-chain gene of yeast with a grossly deleted version, prepared *in vitro* using restriction enzymes. Spores carrying only the deleted clathrin gene do not synthesize any clathrin heavy chain or even any immunologically cross-reactive material, yet they are quite unexpectedly viable, although they grow more slowly than wild-type cells. The only indication of a defect in the cells is an accumulation of vesicular structures in the cytoplasm and the presence of a larger than usual intracellular pool of invertase, which, however, is secreted at essentially normal rates.

What could this mean? As the authors suggest, one possibility is that although biosynthetic transport does not require clathrin-coated vesicles in yeast, endocytosis still does. If so, this would fit well with the evidence from animal cells that clathrin may not be needed for constitutive transport from the endoplasmic reticulum through the Golgi complex to the cell surface. (It is not known whether proper vacuole formation is needed for yeast to grow; also, yeast does not store secretory products.) Another possibility would be that there is a 'back-up' system — an alternative clathrin-like molecule that can replace clathrin when needed, or an alternative pathway that can salvage transport. If so, the back-up coat protein must be structurally dissimilar from clathrin proper, since there is but a single clathrin gene and no cross-hybridizing DNA even under conditions of low stringency, nor any other polypeptide that cross-reacts with antibodies to clathrin. A final, and even less comfortable, possibility is that clathrin is not required to form the vesicles that it normally coats, nor for their utilization. This would be truly heretical but cannot be dismissed out of hand.

These unexpected developments add a breath of fresh air and excitement, and suggest that we are about to obtain a more sophisticated view of the process of protein sorting. They also serve as a reminder that generalizations in cell biology can be more dangerous to the health of the investigator than to that of the organism. □

Geology

Are komatiitic lavas voracious?

from Robert W. Nesbitt

KOMATIITE lavas are highly magnesian silicate rocks which are mainly restricted to the first half of the Earth's history. First recognized less than twenty years ago, in the 3,500-Myr-old Barberton greenstone belt in South Africa[1], they have since been identified in most continents where volcanic greenstones are exposed. They are particularly interesting for their restricted but economically important association with Fe–Ni–Cu sulphides: the most important deposits always occur at the base of the first flow of any komatiite lava pile[2]. Huppert *et al.*[3] have put forward a model in which this association is explained by thermal erosion. In a paper on page 136 of this issue, D.I. Groves and colleagues provide an example of this but one which, paradoxically, reinforces previous criticisms of the model[5].

Komatiite flows consist of an underlying olivine cumulate zone overlain by a zone of skeletal (or spinifex-texture[6]) olivine — that is, olivine set in a matrix of skeletal clinopyroxene and glass. Overall, the grain size and morphology of the olivine changes from a random arrangement of olivine plates with fine-grain size at the top of the flow to a coarse-grained parallel plate-like arrangement just above the cumulate zone (Fig. 1*a*, *b*). These textures, together with geochemical and experimental data, have led to the concept that komatiitic liquids erupted at temperatures of 1,600 °C, some 300–400 °C above those observed for basaltic flows[7].

Based on these data, Huppert *et al.*[3] speculated that, because of their low viscosity, komatiite liquids would display turbulent flow rather than the laminar flow typical of lower-temperature silicate melts. Their calculations suggested that this would result in high temperatures being maintained at the base of flows, so that the komatiite liquids would be capable of thermally eroding the underlying rocks. Consequently, the komatiite flows might create their own channels and, as a result, assimilation of underlying material could take place.

This new concept also provided an explanation for the occurrence of Ni–Fe–Cu sulphides at the base of komatiite flows. If sulphide-bearing sediments were assimilated they would immediately form an immiscible sulphide liquid, because sulphur has low solubility in silicate melts. The liquid would then scavange Ni and Cu out of the komatiite melt and the resultant Ni–Fe–Cu sulphide liquid would settle into topographical lows at the base of the komatiite flow, which itself was still molten. Although the sulphide–silicate immiscibility model was not new, this scheme provided an explanation for the origin of the sulphur and for the channel or trough-like structures, which are a prominent feature of almost all komatiitic nickel sulphide deposits.

In a further twist to the complexities of komatiite-sulphide genesis, Groves *et al.*[4] now suggest that the thermal-erosion model only works if a pool of sulphide liquid already exists — the sulphide providing the high thermal-conductivity medium necessary to intitiate melting in the underlying rock. Their evidence comes from the hanging-wall ore bodies at Kambalda, Australia, which are unusual in that they are found between flows higher in the section rather than at the base of the first flow. Groves and colleagues have examined spinifex-textured olivine–sulphide associations that occur in komatiite flow-top zones, just below the massive hanging-wall ore bodies. In these occurrences (Fig.1*c*), sulphide occupies the inter-olivine areas; the authors claim that this represents a replacement of the pyroxene and glass that normally occurs there. The main evidence sems to be the occurrence of types transitional between all-sulphide and all-silicate inter-olivine material, interpreted as the result of selective melting in the spinifex zone of the komatiite flow by the transference of heat through the sulphide pool from the overlying komatiite flow. The resulting silicate liquid was then displaced upwards from between the olivine grains by the overlying heavier sulphide, which settled into the space that was previously occupied by pyroxene and glass.

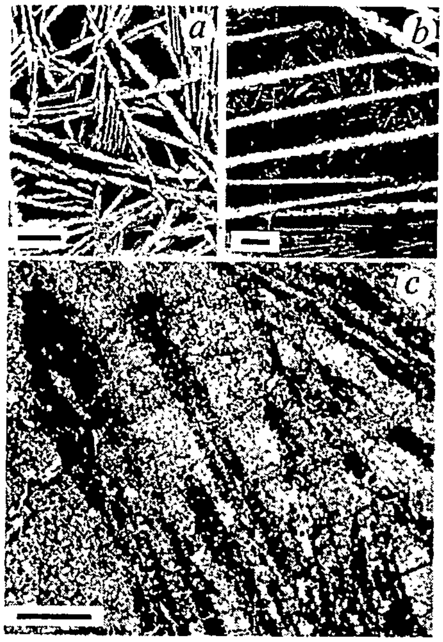

Fig.1 *a*, Thin section of a komatiite with random spinifex texture. Olivine (white) plates separate areas of glass and clinopyroxene (dark areas). This textural type is commonly found close to the upper surface of flows. *b*, Thin section of a komatiite with plate spinifex texture. The long light-coloured crystals are olivine with the inter-olivine areas occupied by clinopyroxene and glass. This is found near the upper surface of komatiite flows but below the random spinifex type shown in *a*. *c*, Polished rock slab showing skeletal olivine crystals (dark) and Fe–Ni–Cu sulphide. These may represent pre-existing plate spinifex-textured komatiite[4].

Furthermore, the fact that the olivine texture in the sulphide is always of the plate type, indicates that the fine-grained random spinifex (commonly found above the plate-type) must have been thermally eroded by the overlying flow. This is a particularly critical observation because Groves *et al.* claim that along strike from the sulphide occurrence, the younger komatiite flow directly overlies either a sediment or a spinifex-textured komatiite with random olivine. In other words, thermal erosion occurred only if a pool of sulphide liquid was present. Hence the paradox — although they provide an example of thermal erosion, Groves *et al.* at the same time caution against the general application of the model.

If komatiite flow on older komatiite does not produce melting without the intervention of sulphide liquid, what about komatiite liquid flowing on to basalt or sediment? Groves *et al.*[4] have looked again at the major nickel ore environment at Kambalda, where massive sulphides occur in trough-structures separating pillow basalts (footwall) from komatiites. Here the evidence for thermal erosion is less definite, despite the undoubted presence of a major pool of sulphide liquid. The problem lies in the lack of specific marker horizons in the underlying pillow basalt sequence that would indicate whether there has been removal of the basalt. Although they admit that the trough structures almost certainly focused thermal erosion through the presence of the sulphides, the authors insist that such troughs are first-order volcanic/topographical features and not the products of thermal erosion

We are thus faced with a major dilemma. According to Huppert *et al.*[3], sulphide pools are generated by thermal erosion in surface channels through assimilation of sedimentary sulphur, whereas Groves *et al.*[4] claim that such erosion takes place only under pre-existing sulphide pools. A possible resolution of the problem may be that thermal erosion took place within the crust — evidence from other lines of investigation, particularly studies of zircon ages in the Kamalda area[8], indicate the influence of crustal contamination. So sulphide contamination of komatiites may have occurred *en route* rather than at the surface.

This solution, however, brings us full circle back to the problem of how to transport a dense sulphide liquid to the surface in a lower-density silicate medium — the outstanding problem in previous models involving mantle-derived sulphide liquids. For academic earth scientists, the tangle of contradictions provides a fascinating research challenge, while exploration geologists continue to puzzle over the problem of why Kambalda komatiites are so richly endowed in nickel sulphides when elsewhere there are only komatiites and sulphidic sediments. □

---

100 years ago

In the twentieth volume of the *American Journal of Science* I gave a preliminary account of my search for the trans-Neptunian planet. I regard the evidence of its existence as well-founded, and nothing has weakened my conviction as to its existence in about that part of the sky assigned; while the independent researches by Prof. Forbes conducted him to an identical result. That five years have elapsed, and the planet is still unfound, is not sufficient assurance to me that its existence is merely fanciful. From *Nature* **33** 258, 14 January 1886.

Cosmic rays

A supernova for a neighbour?

from Arnold Wolfendale

COULD a supernova have exploded recently on our doorsteps? Don Clayton, D.P. Cox and F.C. Curtis think so. In *The Galaxy and the Solar System* (University of Arizona Press, in the press), they suggest that a supernova explosion occured 15 pc away — only ten times the distance to the nearest star — about 10^5 years ago. If this controversial claim is correct, it could help to explain the origin of cosmic rays.

It is remarkable that 75 years after they were discovered by Victor Hess, researchers still argue about where cosmic rays come from. The seemingly incessant rain of cosmic rays that bombard the Earth consists of atomic nuclei, protons, electrons and about one part per million of γ rays. This tiny γ-ray component is proving of considerable value to researchers because γ rays travel in straight lines, unlike the particles, which follow tortuous paths in the tangled magnetic fields of the Galaxy. Because many of the γ rays seem to be produced by the cosmic-ray particles interacting with the gas in the interstellar medium (ISM), they can be used to probe the spatial distribution of the particles and thus give a hint as to their sources.

Although some particles achieve enormous energies — up to 10^{20} eV, compared with about 10^{12} eV in the giant accelerators — it is the lower-energy particles that are of concern here. Among the many contenders for their generation, supernovae (SN) — exploding stars, typified by the well-documented Crab Nebula of 1054 — are currently the favourite. Although they were first suggested as cosmic-ray sources in 1934, problems arose because the cosmic ray particles were supposed to lose energy in the ensuing supernova remnant (SNR). Recent advances have, however, included clever ideas on how shock waves can transform shock energy into cosmic rays with high efficiency so that the cosmic-ray energy in a SNR increases rather than falls with time. Support has come from claims that a comparatively nearby old remnant, termed the Loop I SNR, has within it a higher cosmic-ray intensity than elsewhere (Bhat, C.L. *et al. Nature* **314**, 515; 1985).

The ideas of Clayton and colleagues on the thorny question of the environment and history of the Solar System are the most recent developments bearing on the origin of cosmic rays. Gone are the days when the ISM was considered to have a uniform density of 1 atom cm^{-3}; now it is thought to have at least three phases differing in density and temperature. Clayton *et al.* propose that the Solar System is immersed in a 'cloudlet', with a density of 0.1 atom cm^{-3} and temperature 10^4 K extending about 1 pc from the Sun, residing in a medium of much lower density and considerably higher temperature (4×10^{-3} atom cm^{-3}, 10^6 K), that extends approximately 100 pc from the Sun. It is in this lower-density medium that a SN is assumed to have occurred only 15 pc away about 10^5 years ago.

The authors point out two factors favouring their proposals: the argument of D.P. Cox and P.R. Anderson (*Astrophys. J.* **253**, 268; 1982) that this could explain the observed soft X-ray flux, and Clayton's own suggestion that the comparatively strong γ-ray line from the unstable ^{26}Al nucleus in the ISM comes from the debris of the SN explosion. This γ-ray line is very interesting as it is the first clear case of a line from radioactive nuclei in the general ISM; it was detected by the HEAO-3 and Solar Maximum Mission spacecraft, both of which recorded fluxes in excess of expectation. ^{26}Al has a half life of about 10^5 years and some is doubtless produced in SN explosions; if a SN were so close and had exploded so recently, little ^{26}Al would have been lost by decay, so that the γ-ray flux could be entirely explained.

What effect would such a SN have on the ambient cosmic-ray flux? The authors expect the present value to be twice the average but I find this difficult to accept. There is now a wealth of data on the gradients of cosmic-ray intensity in the Galaxy, obtained by satellite studies of γ rays above 100 MeV, and an excess much more than 30 per cent would be difficult to accommodate, at least in the important proton component. Problems also arise with the relative numbers of cosmic-ray 'nuclei' more massive than protons, in particular with the 'grammage' distribution, which is an indicator of the amount of ISM through which the cosmic rays have passed. Clayton's group are able to get round these difficulties by involving four components of the cosmic radiation that have achieved their energies in different ways in the remnant and in the supernova itself — but this seems a rather contrived solution.

Where, then, does all this leave the problem of cosmic-ray origin? It seems increasingly possible that supernova shocks accelerate a significant fraction of the low-energy cosmic-rays. Although a supernova as recent as 10^5 years ago and as close as 15 pc seems unlikely, some of the ideas put forward by Clayton *et al.* for explaining outstanding anomalies in related areas are worthy of much more detailed study. □

Gene regulation

Importance of helical periodicity

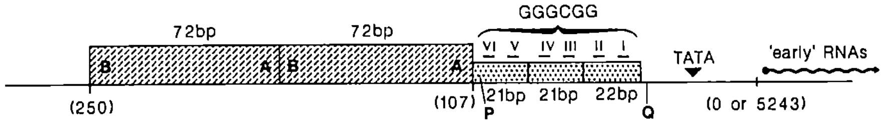
from Tariq Enver and Roger Patient

ATTEMPTS to understand transcription of eukaryotic genes by the enzyme RNA polymerase II have so far focused either on the identification of the sequences that together constitute the gene promoter or on the proteins (*trans*-acting factors) that recognize these sequences and are necessary for transcription. A paper by Takahashi *et al.* on page 121 of this issue[1] demonstrates that the static arrangement of the promoter sequences is an important parameter for transcription. The authors suggest this may best be interpreted as reflecting a role for protein – protein contacts in promoter activation.

Broadly speaking, RNA polymerase II promoters are organized according to a common modular plan[2]. The 'TATA box' specifies accurate initiation of transcription from a position 25–30 base pairs (bp) downstream (of itself). Additional 'upstream elements' important for efficient transcription are located within 100 bp of the transcription start. And transcriptional activity may be further modulated by an enhancer element. As shown in the figure, the 'early' promoter of simian virus 40 (SV40) conforms to this general scheme. The upstream elements appear in the form of six GC-rich sequence motifs, two each within the three 21 / 22 bp repeats; a pair of 72 bp repeats constitute the enhancer element.

Takahashi *et al.*[1] have tested the effects of altering the stereospecific relationships of these three promoter elements of SV40 by making insertions of odd or even multiples of 5 bp — about half a turn of the DNA helix — either between the enhancer and 21 bp repeats (site P in the figure) or between the 21 bp repeats and the TATA box (site Q). Strikingly, insertions at either site that maintain the helical pitch relationships of the promoter have little effect on transcriptional efficiency, whereas those that alter it reduce transcriptional efficiency by up to 10-fold. One interpretation of the importance of the helical disposition of the promoter elements is that it facilitates contacts between the *trans*-acting factors that bind at the SV40 promoter elements[2,3], and/or that it provides the appropriate recognition surface for RNA polymerase II.

Precedent for the involvement of protein – protein contacts in the regulation of gene expression comes from studies on *Escherichia coli*. The elegant work of Ptashne and coworkers[4] has clearly demonstrated that whereas repression by bacteriophage lambda repressor (cl) protein is mediated by steric exclusion of RNA polymerase, the simultaneous stimulation of the adjacent, divergently transcribing promoter for the *cl* gene itself is mediated by protein – protein contacts between the repressor and RNA polymerase. The proximity of the binding sites for activator proteins and RNA polymerase in the galactose[5] and arabinose[6] operons also suggests that activation occurs by protein – protein contacts. However, one of these activator proteins, the cyclic AMP receptor protein, acts on several operons, and the portions of its binding sites relative to the promoters are variable, thus calling into question whether induction always works by protein – protein contacts.



Schematic diagram of the simian virus 40 'early' promoter.

What other explanations are possible for the helical periodicity observed by Takahashi *et al.*? One possibility currently attracting attention is DNA bending. From studies of trypanosome kinetoplast DNA, Wu and Crothers have pointed out that the sequence elements causing the axis of the helix to deviate must be arranged at intervals approaching 10.5 bp if the sum of the helical deviations is to result in a bend[7]. Bending may be an important component in defining the binding site of a *trans*-acting factor. Work on the positioning of nucleosomes on DNA[8] provides evidence that bending is important for protein – DNA interactions and it may well also act to facilitate protein – protein contacts. Such a mechanism has been suggested for the induction of the lactose operon of *E.coli* by cyclic AMP receptor protein, which induces DNA bending on binding to its recognition site and may thereby facilitate contacts with RNA polymerase[7].

Alternatively, the observed helical periodicity may reflect a requirement in factor binding for the stereospecific alignment of two or more altered DNA structures. Possibly relevant in this context is the identification of Z-DNA segments in the SV40 72 bp repeats[9]. Another quite attractive explanation would involve the interaction of the promoter with the nucleoskeleton[10]. Attachment along one face of the helix could block access of transcription factors to that face and the extent of blockage would vary with periodicity.

Particularly intriguing is the requirement for stereospecific alignment between the enhancer of SV40 and its 21 bp repeats. Might this shed light on enhancer mechanisms, and can it be reconciled with the fact that enhancers potentiate transcription from their promoters in a way that is essentially independent of orientation, distance or position relative to the gene[11]? In their paper, Takahashi *et al.* cite as yet unpublished evidence from their group[12] that each 72 bp enhancer motif contains two distinct binding domains (A and B in the figure). If, as their data imply, the important protein – protein interaction is between factors bound at A and the 21 bp repeats, then reversing the orientation of the enhancer with respect to the 21 bp repeats might be expected to perturb the critical factor interaction.

Takahashi *et al.* suggest that action at a distance could still be mediated by protein – protein contacts if the interposing DNA is looped out[2,11]. Possible examples of this type of mechanism have been found in the galactose and arabinose operons of *E.coli*, where it has been suggested that repressor monomers bind at two well-separated sites and monomer – monomer interactions facilitate DNA loop formation[13,6]. Interestingly, insertions between the two binding sites in the arabinose operon show the same helical periodicity as described by Takahashi *et al.* for SV40.

Although DNA loop-out seems a reasonable model for enhancer action from a distance upstream of the promoter, the model is sterically unattractive for a downstream enhancer. An attractive modification to the model is that the loop forms only transiently to facilitate intramolecular factor transfer. But, although upstream enhancement has been demonstrated *in vitro*, downstream enhancement has not, suggesting that simple factor transfer cannot be the whole story. The magnitude of enhancement *in vitro* is only about 10-fold[14] whereas it is 100–1,000-fold *in vivo*. Interestingly, the transcription level seen *in vivo* by Takahashi *et al.* varies with insert size over the range of variation seen *in vitro*. Thus, it is possible that both may be reflecting only one component of the proposed biphasic nature of the 72 bp repeats, whereby they act as both an enhancer and an upstream promoter element at short range but just as an enhancer at long range[15]. The helical periodicity and *in vitro* effects may be due to their action solely as a promoter element. It is tempting to suggest that domain A in the 72 bp repeats is the promoter element and domain B is the enhancer. One could then predict that domain B could be completely separated from domain A with little loss of activity; in fact, 50 bp seems to be the upper limit[12]. ☐

Plate tectonics

Microplates in Antarctica

from A.K. Martin

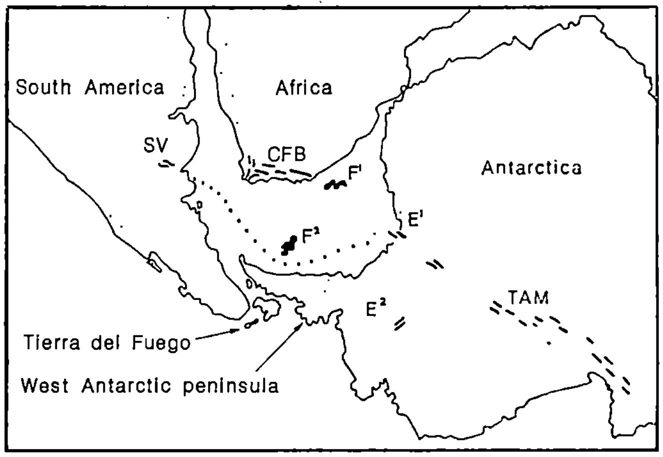
Two basic schools of thought have emerged on how Antarctica, and particularly West Antarctica, fitted against southern South America before the break-up of Gondwanaland. One suggests that Patagonia and the Falkland Plateau fit into the Weddell Sea, implying that East and West Antarctica have formed one plate since the Jurassic[1,2]. The other places East Antarctica against Mozambique and overlaps West Antarctica with the Falkland Plateau[3,4]. This overlap, which was considered unacceptable, implies that West Antarctica has moved relative to East Antarctica and thus formed a separate plate or several microplates during early break-up[5]. Palaeomagnetic evidence supported the existence of West Antarctica microplates[6]; in this issue, Mitchell *et al.*[7] provide more evidence for microplates in this region, not from West Antarctica but from the Falkland Islands on the present-day South American plate.

A wealth of seafloor spreading and fracture zone data substantiate that the Falkland Plateau has been part of the South American plate since the initiation of the South Atlantic[8,9] — its palaeoposition 125 Myr ago is well constrained. The new palaeomagnetic work, however, suggests that more than 190 Myr ago the Falkland Islands were adjacent to the Transkei coast of South Africa and that a rotation of 180° occurred between 190 and 125 Myr. As originally suggested by Adie[10], this palaeoposition aligns the Lafonian diamictite of the Falklands with the Dwyka tillite of South Africa, which forms the effective demarcation of the northern front of the Cape Fold Belt.

Although the authors concede that much more palaeomagnetic, geochronological and structural work is required to confirm the reconstruction[7], their work has much wider implications for the geology of the area. First, if the Mozambique palaeoposition for East Antarctica is adopted, then a curvilinear mountain belt (the Gondwanide orogen of Du Toit[3]) would have stretched from the Sierre de la Ventana in South America across the Cape Fold Belt in South Africa to the Trans-Antarctic mountains[3,11] (see figure). In their rotated positions, the Falkland Islands and the Ellsworth Block complete the chain — if left unrotated, they would necessitate large re-entrants in the mountain belt. Proponents of a more southerly palaeoposition of a single-plate Antarctica used such re-entrants as criticisms both of this refit and of the philosophy of aligning mountain belts[12]. Their objections now fall away.

Debate has also centred around the plate-tectonic nature of the Gondwanide orogeny. The Cape Fold Belt and its intercontinental correlates are seen as constituting a back-arc basin, with the fore-arc and magmatic terranes extending from Chile through Tierra del Fuego to the West Antarctic peninsula[11]. These latter areas are considered the source of volcanic detritus found in foreland basins on the Gondwanide continents. An alternative view is that the Cape Fold Belt, in particular, represents an intracratonic orogeny; there is a lack of nearby fore-arc or magmatic features, the metamorphic grade is low, and the small amount of crustal shortening is considered incompatible with fast-moving colliding plates[13,14].

But the stable craton of Gondwanaland must include the 1,000-Myr-old Cape Meredith complex in the Falkland Islands. The Lower Cretaceous palaeoposition of the Falklands implies a south-westward bulge in the craton and the fore-arc terranes of Tierra del Fuego — 1,500 km from the Cape Fold Belt — is considered too distant for the two areas to be linked by subduction-related orogeny[13], unless some extreme form of 'flat-plate' or low-angle subduction occurred. The rotation of the Falkland Islands to the eastern margin of South Africa removes the bulge in the craton, opening up a space in the Jurassic reconstruction (see figure) that may have been occupied by West Antarctic microplates. The distance between fore-arc terranes and the Cape Fold Belt may therefore be considerably reduced. The alignment of the fold vergences of the Falkland Plateau and the Ellsworth Block with the rest of the Gondwanide orogeny also weakens the argument[14] that large variations in fold vergences are more typical of mobile belts within continental crust than subduction-related orogenies.



A new reconstruction of Gondwanaland[19] showing the Lower Jurassic (F^1) and Lower Cretaceous[9] (F^2) palaeopositions of the Falkland Islands. Also shown are the rotated (E^1) and unrotated (E^2) positions of the Ellsworth Block within Antarctica[6]. The dashes represent the Gondwanide Orogeny: SV, Sierra de la Ventana; CFB, Cape Fold Belt; TAM, Trans-Antarctica Mountains. The dotted line represents the southwestern bulge of the Gondwanide craton caused by the Falkland Islands in their Lower Cretaceous (F^2) palaeoposition, which is removed if the rotated (F^1) position is adopted. Note that the West Antarctic peninsula is shown in its present day position.

Although the rotation of the Falkland microplate solves some problems in south-western Gondwanaland, it raises a whole batch of new questions. How did the Falkland Islands move south-westward and rotate to their Lower Cretaceous palaeoposition? Was the movement associated with the mid-Jurassic–Cretaceous formation of the Outeniqua Basin that underlies the southern continental margin of South Africa and its apparent continuation in the central basin of the Falkland Plateau[15]? Is there some oceanic crust under the central Falkland Plateau[16]? In short, how was the Lower Cretaceous Falkland Plateau constituted?

There is evidence that some movement occurred between the South American mainland and Africa shortly before the South Atlantic opened. Pre-mid-Jurassic palaeomagnetic poles[17] suggest that South America occupied a position about 300 km west of its palaeoposition next to Africa, as shown in the figure, a position almost identical to the one it occupied in the mid-Cretaceous after 10–12 Myr of seafloor spreading in the South Atlantic[9]. This suggests that there may have been separation between the two continents followed by closure before the Lower Cretaceous opening of the South Atlantic. Did such movements involve all of South America or was there relative movement between additional microplates within southern South America? Were these movements similar to or even associated with mid-Jurassic–lowermost Cretaceous (pre-Barremian) back-arc basins in Patagonia and Tierra del Fuego?[18].

All the microplates in the area have still to be identified and their palaeopositions solved. Moreover the configuration of the Patagonian and West Antarctic subduction zones and their relationship to Gondwanaland break-up is not yet known. The subduction of varied oceanic features could have led to the offset of spreading ridges around southern Africa by long transform faults, or complicated microplate tectonics and subduction could provide an explanation for the change in vergence between the Cedarberg and southern limbs of the Cape Fold Belt.

Answers may lie in new marine geophysical data from key areas of the southern ocean and in comprehensive palaeomagnetic, petrological, structural and geochronological studies of the various plates. The new work on the Falklands microplate shows that a different approach to an apparently simple reconstruction reveals a more complicated reality. ☐

Pauling's model not universally accepted

SIR—John Maddox[1] has announced that Linus Pauling "has once more thrown a cat among some pigeons". This cat is a model of directed multiple twinning of a cubic crystal that Pauling[2] insists is the explanation of quasiperiodic crystals with icosahedral symmetry. Pauling's model is specific enough to be contradicted by many experimental observations from high resolution and dark-field transmissions electron microscopy, field ion microscopy, Mössbauer spectroscopy and various electron diffraction methods, most of which have been published.

For a twin model to be meaningful, the size of the individual crystals of the twin must be at least as large as the lattice parameter of 26.73 Å proposed by Pauling. The model is thereby trivially dismissed through a careful examination of the evidence already published of the high resolution (2 Å) transmission electron micrographs[3-7] which show neither twins nor cubic unit cells. There are also detailed companion diffraction data from single icosahedral orientations akin to a conventional single-crystal pattern[3-9]. Had Pauling taken the single crystal diffraction pattern of his predicted structure, rotated it into the 20 different orientations of his twinning model, and superimposed them, he would have seen immediately that his model fails to reproduce these observed diffraction patterns. Happily, contemporary crystallography has these exacting tools available to develop and verify proposed structures.

One of the most compelling observations to contradict the twinning hypothesis comes from field ion microscopy in which individual atoms are resolved[10]. The icosahedral symmetry is seen to extend over the entire field of view. Any twinning of crystals would have been observed and would have altered the symmetry.

From the beginning we viewed twinning as the obvious model within conventional crystallography[8,9] for explaining our observations. Five-fold twins of the equilibrium orthorhombic Al_6Mn phase are occasionally seen in electron microscopy and easily identified as such (D. Shechtman, unpublished data and ref. 11). Micro-diffraction from areas containing equal amounts of all the twins gives a five-fold pattern, which is clearly indexable as coming from periodic crystals and which is different from that of the icosahedral phase. As predicted, dark-field imaging from different spots in turn highlights each twin separately. Microdiffraction away from the twin boundaries clearly reveals single-crystal diffraction. However, for the icosahedral solid dark-field imaging from any spot highlights the entire grain[9]. With such evidence, supplemented by convergent beam diffraction[9,12], twinning has, for some time, ceased to be a tenable hypothesis, even for small unit cells.

Pauling has nonetheless highlighted, however inadvertently, both the ongoing intense search for models of this structure and the basic questions this poses about crystallography. Crystal periodicity has been elevated from a nineteenth century hypothesis of crystallography to the status of a law or an axiom in spite of the well-known existence of incommensurately modulated crystals. In a thought experiment any finite structure can be reproduced and stacked in a periodic array. We could make a periodic model of a glass or of the icosahedral solid by taking a large enough cube, reproducing it exactly and stacking it. If the "unit cell" is large enough, this "periodic crystal" would be experimentally indistinguishable from a glass or the icosahedral solid. Such a large unit cell model would not need to be twinned as it contains internally the required symmetry approximately.

As an aside it should be noted that, because of defects, most conventional real crystals are not truly periodic, but crystallography ignores this and recognizes the ideal. Would it then matter if the artificial periodicity of the large unit cell models was also destroyed by defects?

We have in our own work[13] used the cut and projection methods[14-17] to generate in a systematic way a sequence of periodic structures of ever-increasing periods which in the limit become truly quasiperiodic. In such a sequence, the order and structural units are apparent on a scale which remains constant once the cell dimensions have become large — that is, as the cell dimension increases, the mesh of the diffraction pattern naturally becomes finer and the diffraction pattern deviates less and less from its quasiperiodic limit. Through these studies we can examine various categories of observable differences between the quasiperiodic phase and its long periodic approximant. This enables us to see which of these are the best indicators of large unit cells. The observations on the icosahedral phase are remarkably accurately fitted by the quasiperiodic limit. Pauling's model, and its attendant requirement for *post facto* twinning, simply does not fit anywhere in this sequence.

The nth member of the cubic approximants has a unit cell which is $4.8281\,\tau^n$ Å, where $\tau=1.618034=2\cos(\pi/5)$ is the golden mean which is an important geometric constant with 5-fold axes. Lattice constants of successive approximants increase by a factor of τ. Many d-spacings in the same direction are observed to increase with this ratio, for example, 1.2765 and 2.060 Å which Pauling incorrectly assigns nonparallel indexings of 20 6 2 and 10 8 2. The fifth approximant is interesting for comparing with Pauling's model. Its lattice parameter is 53.545 Å, exactly twice Pauling's. In this cell the 2.168-Å d-spacing which is known to lie along the 5-fold axes has indexes 13 21 0, and for the m3 cubic point group has the 12-fold multiplicity required for icosahedral 5-fold axes. The exact 5-fold direction for icosahedral symmetry is $\langle 1\ \tau\ 0\rangle$. The ratio 21/13 of two successive Fibonacci numbers is an approximant to τ. The angles between the $\langle 13\ 21\ 0\rangle$ are close to what is required for icosahedral symmetry. There is no need to twin this structure to approximate icosahedral symmetry! On the other hand, Pauling assigns 12 2 2 to this spacing, that is, 24 4 4 on the doubled cell. It occurs in 24 different directions in just one of his 20 crystals. In his twinned structure the 480 spots with this d-spacing would occur in either 60 or 120 clusters depending on how much strain he allows. There are too many of them and they do not lie along the twelve 5-fold directions. Comparison with all the fifth approximant indexing shows that only the first two of Pauling's assignments are correct.

Because powder patterns are obtained from many crystals of all orientations, they do not reveal the rotational symmetries as graphically as do single-crystal patterns. By focusing on powder patterns alone, Pauling could attempt to ignore the 5-fold axes. But even the powder diffraction method reveals that many pairs of d-spacings are in ratio of the golden mean and more exact patterns would have required him to keep increasing his unit cell.

John Maddox[1] marvels at "how intuition, experience and apparently universal knowledge can be used to fashion a complicated and unknown crystal structure out of thin air". Unfortunately, complicated crystal structures cannot be fashioned out of thin air. However, Pauling's stochastic method is justly famous when the proper building blocks are used. Pauling's basic building block of aluminium dodecahedra containing the transition element at its centre was wrong chemically. It has been ruled out by Mössbauer measurement on the icosahedral phase[18]. This building block does not occur in any of the known structures of periodic crystals of aluminium with manganese, or with manganese and silicon. The ternary combination may indeed contain packing units quite similar to those that occur in the icosahedral phase[6,19], and Pauling's method using these units may be more successful.

Experimental evidence is a convincing tool for ruling out models. There is by now a wide variety of experimental evidence to rule out both twinning of any sort and all structures of conventional periodic crystals except for those near the limit mentioned above. Pauling's model can only claim a reasonable fit to the X-ray powder pattern data and is contradicted by everything else. The cat was dead. In spite of the commotion, the pigeons will endure.

SIR—The icosahedral phases of alloys such as Al/Mn recently reported by Shechtman and others[1] and amply confirmed by several other groups, present many problems which are compounded by Pauling's demonstration[2] that the powder patterns can be explained as being due to a cubic structure (with $a = 26.74$ Å) which he postulates in some detail. I believe that some puzzling aspects of the situation can now be resolved.

There are two major viewpoints: (1) that the icosahedral phase is a materialization of the Penrose pattern and (2) Pauling's view, that the phase is a result of the twinning of cubic crystallites. I sketch here my reasons for preferring the former.

Normal crystal phases fall into one or other of the 230 space groups. Their diffraction effects have the three-dimensional point symmetries which are one or other of the 32 crystallographic point groups. The diffraction symmetry of the icosahedral phases is m35, which is not one of the 32 crystallographic point groups and thus the real space structure giving rise to the diffraction cannot be that of a normal crystal. What then is it? I assert that it is a particularly fine-grained and highly ordered texture corresponding to what might be called an 'icosahedral coincidence site lattice'. This might also be seen[3] as an icosahedral nematic, again perhaps the most ordered possible.

High resolution electron micrographs produced by several groups show no signs of the twin boundaries which would be necessary for Pauling's model. Twinning must therefore be at a near to atomic level.

The basic physical observation[4] is that the diffraction patterns show that there are three strong coplanar reciprocal lattice vectors (corresponding to planes of spacings 2.168, 2.060, 1.2765 Å) which lie in the directions of the 5-fold, 2-fold, 2-fold axes of a dodecahedron, respectively, and that the first is half the vector sum of the others. The indices (12,2,2), (10,8,2) and (20,6,2), allocated by Pauling, are incompatible with this. Further, Pauling allocates to strong reflections in the ratio of $1{:}\tau{:}\tau^2$ the cubic cell indices with $n = 64$, 168 and 440 which are close to the squares of 8, 13 and 21 from the Fibonacci series, but he neglects the angular relationships between the strong reflections. (Note: τ is the golden number $(1 + \sqrt{5})/2$.)

The effect of strong structure factors for planes, which would be the $(\tau, 1, 0)$ planes in a cubic cell (parallel to the faces of a regular dodecahedron), is to produce two periodicities, in the incommensurable ratio of τ, along the 2-fold axes. The published electron micrographs clearly show this irregularity. From this, everything else flows. In order to have a material structure with two such overlapping periodicities there must be a determinate or statistical rule to decide which has precedence at a particular site. The Penrose tiling is such a determinate rule.

The Penrose tiling gives a convincing indexing of the diffraction patterns[4,5], but leaves open the problem of placing atoms in the quasi-unit-cells, for which various suggestions have been made.

The essential geometry is to be found in the demonstration by Euclid that five cubes may be inscribed in a regular dodecahedron. Pauling emphasizes the cubic nature of the twinning, but gives no guidance as to how it may be continued indefinitely. The quasi-crystal view emphasizes the icosahedral quasi-lattice and provides an algorithm for indefinitely great extension.

The twin relationship arising from seeing five cubes inscribed in a dodecahedron, means that along the 5-fold axis all five cubes are viewed in the $[\tau, 1, 0]$ direction. In the three-fold view, two cubes (related as a $\Sigma = 3$ coincidence site lattice) are viewed along [111] and three along $[(1 + \tau), 1, 0]$ and in the 2-fold direction [100] for one cube and $[\tau, 1, 1/\tau]$ for four cubes. We may ask how the five structures intersect as a finite grouping and how such an arrangement may be extended.

The diffraction effects of the icosahedral phase thus resemble those of a twinned cubic texture, of a Penrose tiling and of an incommensurate structure. A quasi-lattice in N-dimensions was originally defined[6] as one where lattice points are arranged with integral coordinates with respect to more than N axes. The hexagonal Miller–Bravais system is a familiar case, but if the axial lattice vectors are incommensurate with each other, then incommensurate periods in the same direction can occur.

We assert that the Penrose tiling can be regarded as: (i) an icosahedral nematic structure, (ii) an icosahedral coincidence site lattice and (iii) a generator of homometric structures. Two structures are homometric if they have the same diffraction pattern but different structures (spatial arrangements of the scattering matter). Thus they have the same set of amplitudes for the Fourier terms but different sets of phases. (We wish to point out that these sets of phases may have symmetries different from that of the point group of the diffraction amplitudes.)

If we take threads along the 2-fold axes then the Penrose tiling may be covered (three times over) by the 15 threads, each rhombohedron being crossed by three threads, each entering through one face and leaving through the face opposite. From this it follows that the spacing of the planes of tiles with a common edge is twice the unit rhombohedral edge. In the Penrose tiling these are planes across the structure parallel to the faces of a regular dodecahedron and at these uniform intervals. The strongest diffraction line corresponds to a spacing of 2.170 Å for these planes. With the indices of Bancel *et al.*[4], this strongest plane would correspond to the layers of tiles, but the edge of the fundamental rhombohedra would be only 1.085 Å. They could thus occur only statistically. On Elser's indexing[5] the fundamental edge would be τ^3 times this, namely 4.60 Å, but the layers would then be 9.20 Å apart and it is then necessary to explain why the strongest Bragg planes have a spacing of $1/\tau^3$ times this.

The nature of the threads remains open but they may be imagined, for example, as icosahedra (of Al around Mn) sharing edges. The Penrose pattern would describe how one set of threads can pass through another.

In view of the production of the icosahedral phase by rapid cooling it is unlikely that the potentiality of the Penrose pattern to prescribe an exactly determinate structure of infinite extent is used. The problem is the classical one of packing dodecahedra which almost fit to fill space.

The diffraction properties of a quasi-lattice are subtle and unexpected. The Fourier transform of an extended one-dimensional Fibonacci series of long and short intervals (in the ratio of τ) is the same as the series itself. This is also the case in more than one dimension, and holds for those arrays of lattice points which can be derived by bounded projection from a lattice of higher dimensionality (an alternative definition of a quasi-lattice)[5]. Determination of the atomic arrangement still, as far as we know, waits for the development of a method of calculating structure factors and for the apportionment of statistical and determinate features of the texture.

Sir—We recently presented X-ray and electron diffraction data on the icosahedral phase of rapidly quenched Al–Mn and introduced a simple indexing scheme based on the symmetry of an icosahedron (Bancel *et al.*, ref. 1 and in the press). We used our X-ray diffraction measurements to argue against models for the structure of this material that require multiple scattering from different crystallites to explain the electron diffraction patterns. Linus Pauling has proposed[2] a new crystalline model for the icosahedral phase, which he compares with X-ray powder diffraction data obtained from Shechtman and Blech[3].

In Pauling's model, the icosahedral symmetry observed in the electron diffraction patterns is accommodated by multiple twinning of cubic crystals. Although twinning makes the analysis more complicated, it is still possible to check whether the (hkl) indices given in Table 1 of Pauling's paper can be consistent with the observed electron diffraction patterns. Consider any two of Pauling's cubic vectors, which are separated by some angle ϕ. Upon twinning, each vector is rotated via a set of icosahedral symmetry operations to a new set of positions. The same twinning operations act upon both cubic vectors, so that the angle ϕ is preserved during rotation. If one now calculates the angle that the vectors of one icosahedral set make with the vectors of the other set, the angle ϕ should certainly appear. Pauling's model fails this test on nearly all counts[1]. Thus, the icosahedral diffraction spots cannot be attributed to rotations of the cubic structure which Pauling proposes.

Pauling states that the agreement between the X-ray peak positions of Shechtman's data and the d-spacings predicted by his model provides compelling evidence that his structure is the correct one. We are not convinced by this argument because we believe that seven of the peaks he indexes are actually due to a different phase present in the sample. We have measured X-ray powder diffraction patterns from a large number of rapidly quenched icosahedral alloys, and find that reflections 3,4,6,8,10,15, and 16 listed in Pauling's Table are due to a contaminant phase that appears when excess Si is present in the sample. These peaks are not found in the electron diffraction patterns. (Note that Shechtman's sample contained several atomic % Si). We feel that this fortuitous agreement of several spurious peaks is an argument for the hypothesis that *any* powder diffraction pattern can be indexed via a sufficiently large cubic unit cell.

The question remains as to whether a crystal structure incorporating a large unit cell might still describe the electron and X-ray diffraction data. Based on recent low angle electron and X-ray diffraction data we can specify a minimum size for any proposed cubic unit cell. For any periodic structure the squares of any two d-spacings must be in integer ratios unless the corresponding diffraction spots have the same symmetry (so are collinear) in which case the ratio of the d-spacings is a ratio of integers. We have observed two such spots which lie along the major axes of the 2-, 3-, and 5-fold symmetry planes with d-spacings of 8.85(7) and 5.42(3)Å, the ratio of which is 1.633. The lowest rational approximate, within experimental error, to this number, is 13/8. This implies a minimum cell size of a_0=8(8.85Å)=71Å. A 27Å cubic unit cell cannot produce two *collinear* spots with these radii even with the inclusion of multiple twinning. Although our arguments are stated in the context of a twinning model, numerous high resolution microscopy measurements vitiate the possibility of twins in these structures. In the absence of twinning our limit of 70Å as a minimum cell size holds and is valid for any crystal symmetry. A crystal structure adhering to this criterion would have to include well over 10,000 atoms in its unit cell.

Finally, we find somewhat curious Pauling's statement that "Crystallographers can now cease to worry that the validity of one of the accepted bases of their science has been questioned". No one has seriously questioned the premise that fivefold or icosahedral symmetry is inconsistent with periodic translational order. Rather, it has been observed that particular arrangements of atoms without simple periodic translational order and with crystallographically disallowed symmetries may nonetheless give rise to sharp diffraction patterns[4]. The study of "quasicrystalline" structures is mathematically intriguing. Furthermore, even if all the phases of Al–Mn should turn out to be crystalline, the theory of quasicrystalline materials may well provide clues to the properties of materials that have local icosahedral symmetry.

Sir—In the analysis of apparent icosahedral symmetry of Al–(Mn–,Fe–) alloys by Pauling[1] one observation remained unaccounted for. Mössbauer data of Swartzendruber *et al.*[2] indicate the presence of two type of sites for the transition metal. The occurrence ratio was found to be close to the golden mean $(\sqrt{5}+1)/2=1.61803$. In the model of an aperiodic "icosahedral phase" this can be easily explained by two types of differently distorted icosahedra. In order to fill the three-dimensional space in the sense of the 5-fold Penrose tile the occurrence ratio of two different elements should be exactly the golden mean.

On the other hand, in the Pauling's picture of multiple twinning of cubic crystal the growth process can be seen as starting from the 12-vertex icosahedral seed (Fig. 1 of ref. 3), with the next layer being dodecahedral (20 atoms). In any structure based on these two mutually complementary polyhedra the occurrence ratio of 20/12=1.667 could be expected for different types of lattice sites. But this ratio differs from the golden mean by only 3%.

A plausible suggestion is, therefore, that Swartzendruber *et al.*[2] did, in fact, observe the above ratio (20/12) rather than the golden mean. If this is the case, then the dilemma between the "icosahedral phase" and Pauling's model based on a cubic cell could be resolved by the Mössbauer experiment with the peak intensity resolution greater than 3%.

Taking culture seriously

Philip Kitcher

Culture and the Evolutionary Process. By Robert Boyd and Peter J. Richerson.
Chicago University Press: 1985. Pp.331. $30, £25.50.

FOR true believers in biology as the key to understanding human behaviour, "culture" is a word that cowards use. Sociobiological zealots maintain that the invocation of culture as an evolutionary force obfuscates Darwin's insight that human behaviour is the product of evolution. At the other extreme are those who refuse to commit social science, protesting that the combined efforts of anthropologists, sociologists and mislocated biologists teach us far less about human nature and human conduct than the observations of a Shakespeare or a Stendhal. Human culture, they declare, is too complex for analysis, and it radically transforms the simple forms of behaviour we have inherited from hominid or prehominid ancestors. Between the militant sociobiologists and the despondent sceptics lies a large territory, explored by a small number of scholars who hope to take human culture seriously and to analyse its evolutionary effects. Robert Boyd and Peter Richerson have charted some of this territory with exemplary skill and determination.

Culture and the Evolutionary Process addresses two general problems. Boyd and Richerson want to understand the evolutionary effects of various systems of cultural transmission, conceived as systems in which individuals may acquire phenotypic characteristics at least partly as a result of imitating any number of cultural "parents" or "models". They attempt to identify the various forces that can preserve or change the distribution of traits across the generations of a population having a system of cultural transmission. Their second general question concerns the possibility of maintaining systems of cultural transmission under ordinary selection.

The second question arises because Boyd and Richerson see their book as a (polite) debate with conventional human sociobiologists. (In my view, the deference is overdone and the differences understated.) If it were shown merely that certain conditions of cultural transmission might lead members of a population to forms of behaviour distinct from the sociobiological optima, then there would be a simple retort: where cultural transmission proves maladaptive, selection will work to eliminate it; hence culture can only be maintained when it helps to amass evolutionary capital; we may fathom human behaviour by looking at reproductive uccess and forgetting culture.

The book tackles its main questions by mathematical analyses and discursive reviews of findings from psychology, anthropology and sociology. The mathematics is intended to pinpoint the conditions under which various kinds of evolutionary processes can occur. In particular, the authors want to specify the circumstances that would allow for characteristics detracting from genetic fitness to become prevalent. Their surveys of the social sciences are to provide motivation for the mathematical models they construct and to suggest that it is possible, even likely, that the conditions for the maintenance of genetically maladaptive behaviour may be met.

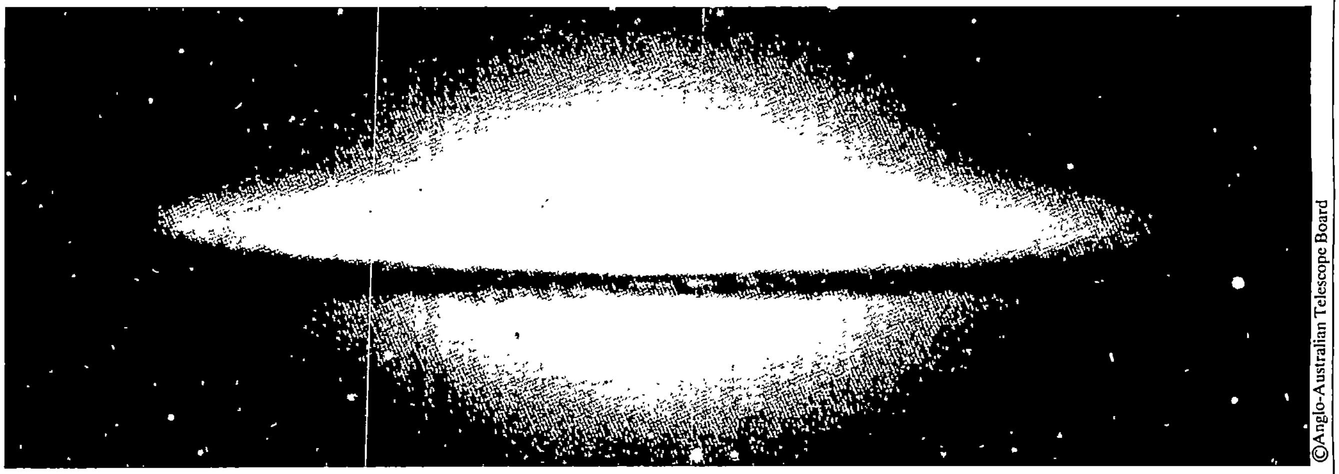
Inspired by Lewontin's well-known account of the structure of population genetics, Boyd and Richerson begin with a representation of an idealized life-cycle in which genetic and cultural transmission jointly affect the distributions of genotypes and phenotypes in descendant generations (pp.5–6). The representation raises at once the obvious possibilities that the book will explore. Does the existence of more than two cultural "parents" make a difference? What are the features of blending and non-blending cultural inheritance? How does imitation interact with individual learning? What happens if the traits that make someone culturally influential differ from those that promote reproductive success? Should we expect that people will be more likely to be influenced by those who have fitness-enhancing characteristics? When will it pay to follow the majority?

The authors develop their basic account of cultural transmission by simplifying ideas worked out in great detail by Cavalli-Sforza and Feldman. Imagine that people are "enculturated" by a fixed number of individuals playing different roles, and that each role has a weight in the transmission of a characteristic. The occupant of each role may have or lack the characteristic. Consider any possible combination. There will be a probability that a person "enculturated" by that sequence of cultural parents will acquire the characteristic. The system of cultural transmission may be identified by specifying the probabilities for all the possible combinations. As the authors note, this approach to systems of cultural transmission allows them to represent both blending and non-blending inheritance.

Analogues of genetic mutation and drift are easily introduced into the basic picture (pp.67–69). But the interesting disruptive forces are those to which Boyd and Richerson devote most attention. The first involves a contrast between individual and social learning. Imagine that the young acquire their adult behaviour by striking a compromise between imitation and individual attempts to learn. If cultural transmission operated unconstrained it would lead them to adopt a certain value of a behavioural parameter; their own efforts lead them to an estimate (possibly error-infected) of the optimal value of the parameter; the adult behaviour expresses a weighted average of the two. Boyd and Richerson show that this scenario involves a force that will increase the frequency of traits favoured by learning, a force they call "guided variation" (pp.95–97). Since the effect of guided variation is adaptive when the individuals are good at determining the best value of the behavioural parameter, it is natural to ask if natural selection will allow for a non-zero weight to be assigned to cultural transmission. The authors give a rigorous demonstration of the intuitive idea that errors in learning and costs of learning may outweigh possible benefits of distrusting tradition. Sometimes the wise child should agree that teachers know best.

Just as guided variation can mimic natural selection, so too can another force that Boyd and Richerson discuss at length. Suppose there is genetic variation with respect to the propensity for imitating traits that lead to reproductive success. Then we can expect selection to favour alleles whose bearers follow the fit. As the authors put it, if guided variation and direct bias were the only forces that shape cultural evolution, then ". . . with the usual caveats, we would be able to predict cultural variation by asking what increases genetic fitness" (p.157).

But it is the power of other forces that is the central theme of the story. Boyd and Richerson propose three ways in which culture can favour the genetically maladaptive. Individuals may base their behaviour on the conduct of those around them. If this occurs, the authors suggest, there may be an analogue of group selection which allows for the evolution of cooperative arrangements. Second, there may be indirect bias, in which some forms of behaviour give a person high status as a model, with the result that other, correlated, traits are also imitated. (Intuitively, the process is analogous to genetic linkage.) Boyd and Richerson offer an analysis of indirect bias, arguing that it can have effects like those of runaway sexual selection. The third force is the simplest. Transmission systems are said to be "asymmetric" if they favour different traits. If the characteristics that make one a successful cultural "parent" are incom-



Edge of darkness: the aptly named Sombrero Galaxy, in Virgo (the "brim" is the dust lanes of the galaxy's central plane). The photograph is reproduced from Peter Cadogan's From Quark to Quasar: Notes on the Scale of the Universe, *recently published by Cambridge University Press, a highly illustrated journey from the human scale to the very large and the very small. Price of the book is £12.95, $24.95.*

patible with some that promote reproductive success, then it is possible for culture to disrupt the smooth workings of natural selection.

The main thrust of *Culture and the Evolutionary Process* can be appreciated by focusing on this last force. Boyd and Richerson construct a sequence of analyses (purchasing decreases in artificiality with increasing complexity) in which they identify precise conditions for the maintenance of a maladaptive trait. As we might expect, selection against the trait has to be relatively weak and the competition for dominant cultural role relatively intense. (The authors tell us *how* weak and *how* intense.) Now comes the sociobiologists' challenge: if cultural transmission is asymmetric with respect to genetic transmission, will selection eliminate it in favour of a system that will reward reproductive success? Not necessarily, claim Boyd and Richerson. For there may be indirect constraints that force certain reproductively successful individuals out of the competition for cultural influence, as well as direct benefits deriving from "enculturation" by a large sample of the local population (pp.188–190).

The authors sum up in a typically modest and cautious way. After noting that their analyses "suggest that asymmetric cultural transmission may cause human evolution to diverge from the predictions of sociobiological theory", they add: "Whether and to what extent it does is an empirical problem" (p.199). More self-congratulatory writers might have seen themselves as constructing a framework within which alternative hypotheses about human behaviour and its evolution could at last be formulated and tested against one another. For what Boyd and Richerson do is to show that there are far more things in the evolutionary process than are dreamed of by most sociobiologists.

Perhaps the chief danger is not that this book will languish unread but that it will serve as the gospel for a new social scientific creed. Reformed sociobiologists may confute their sceptical opponents by announcing that Boyd and Richerson have solved the problem of culture. But the authors themselves claim far less, and rightly so, for there are important questions on which they touch either scantily or not at all.

Consider the focus on cultural transmission. Quite early on, Boyd and Richerson commit themselves to the idea that "culture can profitably be viewed as a system of inheritance" (p.19). But is the entire effect of culture on human evolution to be represented in terms of the transmission of traits that individuals can acquire or reject? Many social institutions are hard to represent in such terms (think of apartheid). Moreover, such institutions frequently have the effect of assigning the members of certain subpopulations to radically different microenvironments with large consequences both for the phenotypes that develop and for the determinants of fitness (again, think of apartheid). Boyd and Richerson step gingerly around the controversy about holism and reductionism without explaining how they plan to treat features of human society such as these.

A second limitation concerns the issue of linkage among cultural traits. One of the banal facts of life is that choices constrain. Certain forms of behaviour preclude others. Moreover, the choices that a person makes are affected both by the actual constraints and those that are perceived to exist. Once these truisms are given their due, we see that there is a type of linkage, possibly important, besides that captured in Boyd and Richerson's indirect bias. To adapt the analogy, the course of evolution at one cultural "locus" may have effects on what happens elsewhere. Further, the ability to free oneself from some constraints might itself be shaped by selection. Perhaps there are adaptive advantages in being able to perceive certain logical and probabilistic connections.

Culture and the Evolutionary Process inherits from traditional sociobiology the habit of treating particular pieces of human behaviour as if they were individually shaped by the evolutionary process. In presenting new mathematical ideas this may simply be pardonable simplification (although the discussion of challenges to adaptationism on pp.282–283 is uncharacteristically superficial). Nevertheless, as social scientists consider the possibility of applying these ideas to aspects of human behaviour, it is crucial to appreciate the possibility that the proximate mechanisms of a piece of behaviour may be implicated in many areas of our social lives. Informative recent studies in descriptive anthropology have sometimes been accompanied by a superfluous and irritating descant to the effect that minute details of behaviour enhance reproductive success. It would be sad if Boyd and Richerson's pioneering efforts spawned a mindless pseudo-adaptationist programme, in which developmental and proximate constraints were ignored and the optima of the new mathematical analyses perceived everywhere.

This book does not iron out a minor wrinkle in the biology of human social behaviour. Rather it addresses one major part of an enormous problem, and it does so with erudition, rigour and imagination. *Culture and the Evolutionary Process* is not easy going, but it deserves a broad readership and a lasting influence. With luck we may one day transcend the dialogue between simplistic reductionism and despairing scepticism. ☐

FIRST CONFERENCE IN JAPAN

◎January 20 ⇛ 22, 1986
◎Keio Plaza Hotel, Tokyo, Japan

ture is pleased to
nounce a conference on
future of molecular
logy and its applications
iotechnology and
dicine, to be held at the
io Plaza Hotel, Tokyo,
January 20-22, 1986.
conference will be
dressed by distinguished
lecular biologists from
United States, Europe
Japan.

e speakers from the
ited States will include
bel Prize winners **James
Watson** *(Cold Spring
rbor)*, who (with F.H.C.
ck) first suggested the
ucture of DNA, and
lter Gilbert *(Harvard
iversity)*.
ier speakers include:
nley Cohen *(Stanford
iversity)*
m Blundell *(Birkbeck
lege, London)*
J. Peacock *(CSIRO,
berra)*
Walter Gehring *(University of Basel)*
Richard Lerner *(Scripps Clinic, La Jolla)*
Sydney Brenner *(Laboratory of Molecular Biology, Cambridge)*
Susumu Tonegawa *(Massachusetts Institute of Technology)*
Shosaku Numa *(Kyoto University)*
Tasuku Honjo *(Kyoto University)*
Ken-ichi Matsubara *(Osaka University)*
Yoshiki Hotta *(University of Tokyo)*
Mitsuaki Yoshida *(Cancer Research Institute)*
Tadatsugu Taniguchi *(Osaka University)*
Hisayuki Matsuo *(Miyazaki Medical College)*
Tokindo Okada *(National Institute for Basic Biology)*
Hal Weintraub *(Hutchinson Cancer Center, Seattle)*

The three main topics to be covered by the conference are

- **Molecular biotechnology**
- **Development and regulation**
- **Immunology and virology**

and the programme is being designed to provide an opportunity for those working in industry, medicine or academic research to bring themselves up to the forefront of research through discussion with world leaders. There will be ample time for questions and discussion. Simultaneous translation services into English and Japanese will be available.

Registration fees:
Y100,000

More than perceptive

P.W. Hawkes

Pattern Recognition: Human and Mechanical. By Satosi Watanabe. *Wiley: 1985. Pp.570. $44.95, £46.*

PATTERN recognition has always been an uneasy subject. There is no obvious definition of "pattern" to fit everything that is grouped within the subject—letters and numbers and the characters of such languages as Chinese and Japanese, chromosomes, ship or aircraft profiles, types of terrain as seen from above, human cell categories, the list is as long as it is varied. It is even more difficult to tie down "recognition", for the idea is closely linked to the human faculty of recognition; the latter is so extraordinary that any attempt to emulate or simulate it at other than a trivial level seems inconceivable. Typists perform stupefying feats of pattern recognition on hand-written material; and once one begins really to think about the problems, it seems that the schoolteacher is performing a much more formidable task in recognizing his new intake of pupils each year than in acquiring his diplomas and degrees.

These difficulties have meant that, unlike most subjects of a primarily mathematical nature, pattern recognition has generated a considerable literature of a philosophical kind, devoted not so much to methods of performing pattern recognition tasks by computer as to understanding what such tasks involve, indeed, to understanding what the brain is doing as it tries to perform them. In this large and difficult book, Professor Watanabe has gone more deeply than most into such questions.

The volume is dedicated "To Dorothea for her patience and cheerful encouragement" and the reader may well sigh for a similar companion for the text is very difficult going, largely because of the language employed: it is inevitable that a young and complicated subject will need some new vocabulary, but it is not necessary to adopt the habits of the least literate kind of sociological writing. All too often Professor Watanabe falls into this style, with the result that some passages are so (linguistically) opaque as to be almost impenetrable. This is sad because, even if obscured by the language in which they are conveyed, the ideas brought together here deserve to be pondered carefully by practitioners of the subject. We are led through a number of ways of regarding the notion of pattern, with a host of down-to-earth examples, ranging from the conceptual (pattern recognition as seeing-one-in-many, as perception, as value-orientated ponderation) to the more overtly mathematical (pattern recognition as entropy minimization, as covariance diagonalization, as discrimination, as structure analysis).

Watanabe expects his readers to work hard, for they must not be daunted by encounters with sensory physiology, classical philosophy or thermodynamic reasoning; they must be at ease with the formidable notation of formal logic; and they must be happy with linear algebra and statistical decision theory. The author does try very hard to explain everything as he goes along, but the more the reader knows beforehand of the tools employed, the more benefit he will gain from the text and the greater will be his admiration for the way the numerous threads are woven together to produce — the metaphor is well-deserved — a very impressive pattern.

This, then, is a rich and densely filled book, occasionally verbose and unconsciously elliptical but exciting and definitely worth the effort demanded in reading it. Pattern recognition will presumably be tamed over the decades as our understanding of the mathematical and cognitive processes involved advances. I suspect that readers who then turn back to their precursors' books will be impressed by the ability of Watanabe to see where the problems lie and to shed some light on their nature at so primitive a stage of the subject. □

Developing concepts

Raymond D. Lund

Molecular Bases of Neural Development. Edited by Gerald M. Edelman, W. Einar Gall and W. Maxwell Cowan. *Wiley: 1985. Pp.606. $85, £87.50.*

RESEARCH on the development of the nervous system has for many years been constrained by techniques which are largely inadequate, especially when compared with the richness of theories offered by early generations of scientists. Now, however, we have the exciting opportunity to define and sequence antigens of developmental significance, to collect cDNA libraries and to study the molecules responsible for assembling the extraordinary structures which make up the nervous system.

There was, therefore, good reason for the Neurosciences Institute of New York, a leading body in the world of the neurosciences, to assemble a symposium around this new research initiative, and to prepare this, its fourth major publication since its inception in 1981.

The book is divided into six sections concerning early development, glia and neurone guidance, neural crest, formation of neurites and synapses, maps and retinotectal system and, finally, gene expression, "primary processes" and behaviour. An elegant introduction by Cowan summarizes the history of work on neural development, and in the last few sentences emphasizes the excitement ahead as this field increasingly becomes the province of molecular biologists.

The introduction is followed by a well-written set of essays by some of the most distinguished investigators currently working in this area. A wide variety of material is covered. For example, given the new insight provided by studies of the adhesion molecule, N-CAM, Rakic has re-examined the field of cerebellar development in which he was heavily involved some years ago. Many articles such as those of Edelman, Letournean, Goodman, Gershon and Schmidt review the current thrust of research in their laboratories. Yet others have reviewed fields to which they have contributed a smaller part. The diversity of approaches and the content of many of the articles make for interesting reading. None of them is dull and most are easily accessible to readers with only a limited background in developmental neurobiology.

As with all volumes which arise from a meeting, the book cannot hope to be comprehensive. However, one wonders, despite the justifications offered, why a fifth of it is devoted to the retinotectal system, a topic that has perhaps suffered from overexposure (and one ironically in which the developmentally significant molecules suggested over 40 years ago still elude identification). Surprisingly, little space is devoted to areas such as transmitter modulation, growth factors, acetylcholine receptor ontogeny, development of cell identity and genetic controls of development.

Indeed the amount of space devoted to molecular biology is quite small. This is in marked contrast to the Cold Spring Harbor Symposium of 1983 on molecular neurobiology. It is a pity also that no one thought to write a summary to balance Cowan's introduction, outlining how our present state of knowledge might be extended and how the approaches presented at the symposium might develop in the light of the recent technical and conceptual advances.

To summarize, it must have been a marvellous symposium and the book presents an elegant set of essays on neural development — among the best of their kind — but it only rarely enlightens on the molecular bases of development. □

Cycling back to the beginning

Michael Whitfield

The Carbon Cycle and Atmospheric CO_2: Natural Variations Archean to Present. Edited by E.T. Sundquist and W.S. Broecker. *American Geophysical Union: 1985. Pp.627. $28.*

It is refreshing — although somewhat disconcerting — for someone involved in the investigation of the contemporary global CO_2 cycle and its possible climatic effects to view the problem from a much broader perspective. This volume jolts the reader into considering such a wider view by presenting a stimulating potpourri of ideas on the direction, cause and consequences of natural fluctuations in atmospheric CO_2 levels over the past 3.5×10^9 yr.

There are more than 40 papers, replete with useful data and providing intriguing insights into the response of different feedback systems to perturbations in the global carbon cycle over timescales varying from tens of thousands to hundreds of millions of years. The papers themselves have been edited thoroughly, and the text is clearly presented and well illustrated. The overall structure, too, is well conceived, in that the contents list is organized into five sections which move progressively further back in time. The first section is intended to link present-day concerns to the geological perspective while subsequent sections take the reader in turn through the last glaciation, the Pleistocene, the Cenozoic, and finally the Phanerozoic and Precambrian. There is a wealth of information here which, however, is unfortunately difficult to dig out because the book has no index and the papers within each section do not necessarily follow a logical sequence. Furthermore the sections identified in the contents list are not explicitly identified in the text, so that the browser finds himself slipping unwittingly from one timescale to another.

The first three sections cover the past 5×10^5 yr and mainly deal with the use of the carbon and oxygen isotope records in ice cores and in deep-sea sediments to elucidate the role of the oceans in controlling fluctuations in atmospheric CO_2 levels. Only one paper deals with the influence of the terrestrial biota on carbon storage. There are many absorbing accounts here of the potential and pitfalls of isotopic techniques for estimating atmospheric CO_2 levels, ice volumes, palaeoproductivity and palaeocirculation patterns. Over this timescale, orbital variations appear to trigger changes in atmospheric CO_2 levels which are, in turn, followed by changes in ice volume.

During the Cenozoic (10^8 yr), processes such as volcanism, tectonic movement, continental weathering and organic carbon burial begin to assume a dominant role. In addition to isotopic clues, crises in the biological record characterized by mass extinctions provide useful markers against which to assess the interaction between the biota and the atmosphere. Surprisingly, only the Cretaceous/Tertiary event is considered here, although the discussion is spiced by the presentation of two conflicting hypotheses (planetismal impact and mantle outgassing).

Geochemical models for CO_2 control in the Phanerozoic are covered in some detail in the final section, but the treatment of the Precambrian is rather sketchy so that only 15 per cent of the book as a whole considers the first 99.75 per cent of geological time! The overall picture suggested is of a punctuated fall from atmospheric CO_2 concentrations one hundred times the present level 3×10^9 yr ago, through a value approximately ten times the present level 10^8 yr ago, to a pre-industrial value only 80 per cent of the present level. The burial and preservation of organic carbon has played a primary role in this decline — a factor which geochemical modellers are now taking into account.

This is a fascinating collection of papers which will repay the effort required for specialist readers to pick their way through such a variety of information. The cost is very reasonable, and one can hope that many individuals will buy the book and use it to help them place the current ferment in atmospheric CO_2 research into a proper perspective. ☐

The Physical Chemistry of Membranes: An Introduction to the Structure and Dynamics of Biological Membranes. By Brian L. Silver. *Allen & Unwin: 1985. Pp.396. £45, $60.*

To present a concise account of all physico-chemical aspects of membranes in a single book, suitable for students and beginning researchers, is difficult because membrane physical chemistry comprises two quite different bodies of knowledge. One centres on the structure and molecular dynamics of the membrane, and includes the physical methods (nuclear magnetic resonance, neutron scattering etc.) used for structural investigations but should also include some account of the molecular interactions that hold the membrane together. The other part centres on the physical chemistry of membrane function, and is chiefly thermodynamic and kinetic in its approach to questions of membrane potential, permeability, and carrier or protein mediated transport. Conventional wisdom suggests that these two fields might be better tackled by separate authors in separate books.

Dr Silver's book attempts to include all these topics but regrettably cannot be recommended for either structural or functional information. Its broad organization is good: 18 chapters with appropriate titles. Within each chapter, unfortunately, there is insufficiency, often chaos, sometimes error, and always a flippant haphazardness as to what is selected for discussion and what is omitted, who is cited and who is not. The entire book has only 378 pages of text which includes 125 figures, many of them full page.

The better chapters are one that deals with order and disorder, as seen by nuclear magnetic resonance and electron spin resonance; one on intermolecular forces, which includes a mathematically detailed section on van der Waals' forces; and one on fluctuations, which includes an introduction to stochastic processes. Order/disorder is in part explained by picturesque images (a box of uncooked spaghetti, a pile of sleepy earthworms) that may be helpful to some students.

The poorer chapters are those that deal with solution physical chemistry (thermodynamics, kinetics, diffusion, membrane potential etc.). For example, the "celebrated Nernst equilibrium equation" is derived, properly limited to boundaries with the same solvent on both sides, only to be applied on the very next page to the equilibrium distribution of an ion between the *membrane interior* and the adjacent solution.

In the next chapter, on passive transport, the author argues as to whether or not diffusion can be regarded as arising from the action of a force. His conclusion is not clear but a subsequent parenthetical statement — "The theoretically inclined will perhaps remember that the diffusion coefficient is related to the autocorrelation function for the random force beating on the molecule" — implies perhaps that diffusion can be regarded in this way. The following chapter is centred on Eyring's absolute rate theory for diffusion, but misrepresents the basic ideas behind the theory by confusing energy and free energy of the activated state.

Silver has a lively style and an instinct for apt imagery. Combination of these assets with more careful theoretical analysis could produce a truly useful book. ☐

Future global warming from atmospheric trace gases

Robert E. Dickinson & Ralph J. Cicerone

National Center for Atmospheric Research, Boulder, Colorado 80307, USA

Human activity this century has increased the concentrations of atmospheric trace gases, which in turn has elevated global surface temperatures by blocking the escape of thermal infrared radiation. Natural climate variations are masking this temperature increase, but further additions of trace gases during the next 65 years could double or even quadruple the present effects, causing the global average temperature to rise by at least 1 °C and possibly by more than 5 °C. If the rise continues into the twenty-second century, the global average temperature may reach higher values than have occurred in the past 10 million years.

THE likelihood of global climate change from increasing concentrations of carbon dioxide is now well known[1-10]. Much more recent is the realization that other less-abundant trace gases are also increasing and that their change is likely in total to have an effect on climate comparable with that of carbon dioxide[11-21]. These include CH_4, tropospheric O_3, N_2O and the chlorofluorocarbons (CFCs) CCl_3F and CCl_2F_2. What do we know about the effect of these gases on climate, their temporal trends, and the implications of these increases? To see how such climate change can occur, we first consider the energy-exchange processes of the Earth–atmosphere system. The relative contribution of the various trace gases to climate change will be determined by their relative contributions to these energy processes.

Solar radiation is absorbed by the atmosphere and the Earth's surface, providing the energy required by many terrestrial processes. Figure 1 shows the amount of energy involved, on a global and annual average. For climate to be in equilibrium, this absorbed solar radiation must be balanced by outgoing thermal radiation. The partial trapping of this thermal radiation by radiatively-absorbing particles or molecules helps to increase surface temperatures by several tens of degrees compared with what they would be without the atmosphere. This process, sometimes called the 'greenhouse effect', occurs largely in the first 10–15 km of the atmosphere, that is, the troposphere. Radiatively active constituents both absorb and emit thermal radiation, depending on their effective cross-sections and on temperature. Their emission varies with the local atmospheric temperature, whereas their absorption depends on the temperatures of the other atmospheric layers and of the Earth's surface where the radiation was initially emitted. Because tropospheric temperatures decrease with increasing altitude, typically by 5–7 °C km^{-1}, the active atmospheric constituents absorb more upward radiative flux than they emit. Clouds and water vapour are the dominant contributors to this process.

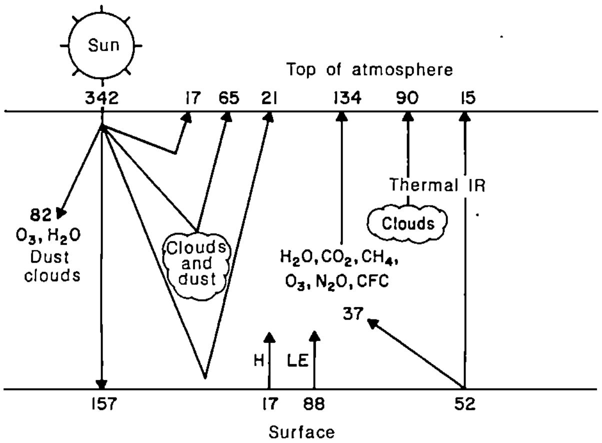

Fig. 1 Schematic depiction of the global and annual average fluxes of radiation within the climate system. Incident solar radiation is either absorbed or reflected as indicated on the left side. Most of the reflection occurs in the atmosphere and most of the absorption at the Earth's surface. Evapotranspiration (LE) and sensible heat fluxes (H) transfer much of the absorbed solar energy to the atmosphere. The absorbed solar energy must ultimately be returned to space as thermal infrared radiation as indicated on the right side. Only the net thermal flux between the surface and atmosphere is shown. Reductions of thermal flux to space from increasing concentrations of trace gases warm the global atmosphere.

What is surprising is that other atmospheric gases, present in minute amounts, in some cases in concentrations <1 part per 10^9 (p.p.b.), also contribute significantly to this trapping of thermal radiation. These gases include, in particular, carbon dioxide, tropospheric ozone, methane, nitrous oxide, and certain chlorocarbons, in order of their present contributions to atmospheric radiative processes. Without the atmosphere's radiatively active constituents, the Earth would lose thermal radiation essentially as a black body at the temperature of its surface, $T_s = 287.5$ K, that is, ~ 387 W m^{-2}, neglecting corrections for the nonlinearity of the black-body emission, surface emissivities <1, and stratospheric effects. The actual radiative flux from the top of the atmosphere is 239 W m^{-2}, so the total amount of trapped radiation is ~ 148 W m^{-2}. Sustained changes in this trapping by as little as 1 W m^{-2} change the Earth's radiative balance sufficiently to be of considerable importance for the climate system. Table 1 shows the current concentrations of atmospheric trace gases and contributions to this radiative trapping.

Table 1 The current 1985 trapping of thermal infrared radiation (ΔQ) by current tropospheric trace constituents

Gas	Current concentration	ΔQ_{total} (W m^{-2})	Ref.
Carbon dioxide	345 p.p.m.	~50	63
Methane	1.7 p.p.m.	1.7	16
Ozone	10–100 p.p.b.	1.3	
Nitrous oxide	304 p.p.b.	1.3	16
CFC-11	0.22 p.p.b.	0.06	19
CFC-12	0.38 p.p.b.	0.12	19

The term ΔQ_{total} is the change of net radiation at the tropopause if the given constituent is removed, but the atmosphere is otherwise held fixed.

The contribution to the Earth's thermal budget of such minute concentrations of trace gases is of considerable interest in its own right. However, the changing concentrations of these gases as a result of human activities[20,21] add a considerable sense of urgency to their study. We review here our current understanding of the radiative properties of the relevant gases, their sources, sinks, and changing concentrations, and the implications of these changes for future climate.

Radiative properties of the atmosphere

Solar radiation of wavelengths from ~0.3 to ~4 μm heats the climate system. Thermal emission at wavelengths from ~4 to ~100 μm, in turn, cools the Earth's surface and atmosphere, ultimately returning the absorbed solar energy to space. The solar radiation is scattered (reflected in all directions) by clouds, aerosols, the Earth's surface, and the major atmospheric molecules (Fig. 1) and absorbed by all but the last of these. Thick clouds act nearly as black bodies in absorbing and emitting thermal infrared radiation, as do also most terrestrial surfaces (an exception is quartz sand with relatively low emissivities[22]).

Of the radiatively active gases in the current atmosphere, only H_2O, CO_2, CH_4, O_3, N_2O and the chlorofluorocarbons (CFC-11 and CFC-12) are in sufficient concentrations to be important in Earth's overall thermal budget. Of these, the strongest absorber by far is water vapour. Indeed, much of tropospheric radiation can be described with water vapour as the only gaseous absorber. Water in either vapour or in cloud form absorbs solar radiation and absorbs and emits thermal radiation. These water vapour states are internal to the climate system, that is, their distributions are controlled by climate processes themselves (that is, the atmospheric hydrological cycle) rather than by sources uncoupled to the climate system. Understanding how water vapour concentrations and cloud radiative properties might change in the future thus requires knowledge of how these terms function as feedbacks in the climate system (a question we shall return to later). Our primary thrust here is to review the role of the other less-abundant trace gases, whose concentrations are being directly perturbed by human activities. Understanding the radiative properties of these gases and their future concentrations is the key to understanding the relative contributions of these gases to climate change.

Ozone is the only other atmospheric gas which absorbs much solar radiation, primarily in the stratosphere. Atmospheric carbon dioxide is but a very weak absorber of solar radiation. The other atmospheric trace gases only affect the atmospheric heat budget through their absorption and emission of the thermal infrared radiation, primarily over the wavelength range ~6–16 μm. Furthermore, at the wavelengths where water vapour strongly absorbs and emits radiation, the effect of other gases is minimal. The vibrational-rotational bands of water vapour thus block radiation at wavelengths <8 μm and rotational bands block wavelengths >18 μm. Carbon dioxide, in turn, dominates the absorption of radiation between 12 and 18 μm.

The remaining spectral region from 8 to 12 μm is known as the 'window' because of the atmosphere's relative transparency to radiation over these wavelengths. The intensity of black-body radiation depends on wavelength according to the Planck function; at the temperatures of the Earth's surface, this function has its maximum values in the window region. Consequently, ~25% of the thermal emission from the Earth's surface (~100 W m^{-2}) is at wavelengths of 8–12 μm. A larger fraction of the emission from the top of the atmosphere is in this spectral range. In this wavelength region, emission varies with temperature T approximately as $\exp(-1{,}500/T)$. A trace gas at a temperature ~33 °C less than that of Earth's emission temperature will thus only re-emit about half as much energy as it absorbs. Because of the presence of clouds, the maximum increase of trapping in the window region is ~30 W m^{-2}.

Interestingly enough, CH_4, O_3, N_2O, CFC-11 (CCl_3F) and CFC-12 (CCl_2F_2) all have strong absorption bands in the atmospheric window region. These trace gases absorb and emit as functions of wavelength in discrete lines with extended wings. These lines occur in bands and result from the rotational splitting of individual vibrational energy transitions of the molecules. Their strength is determined from the strength of the band transitions, from the concentration of the trace gas, and from the rotational partitioning of the band into individual lines. The emission rate of a line depends on its absorption strength and on local atmospheric temperature.

The weakest lines absorb radiation significantly only in their line cores, and this absorption increases essentially linearly with concentration of the absorber gas. Somewhat stronger lines absorb radiation mostly in the wings, with only relatively small amounts absorbed by their saturated cores. Increasing absorber concentration pushes the peak absorption farther into the line wings so that wing absorption increases with the square root of the product of atmospheric pressure and absorber concentration. With even stronger line strengths, the peak absorption is pushed so far into line wings that other lines within the band overlap the absorbing wings and absorption only increases logarithmically with increasing absorber concentration. The absorption of a band varies with absorber concentration according to the variation of its stronger absorbing lines.

The chlorofluorocarbons CFC-11 and CFC-12 and tropospheric ozone are present in such small concentrations and have so many individual lines that their absorption of thermal radiation is nearly proportional to their concentration. Methane and nitrous oxide, being relatively more abundant, increase their absorption essentially according to the square root of their concentrations, whereas carbon dioxide absorption is proportional to the logarithm of its concentration. All the trace gases absorb not in single bands but in multiple bands, and weaker hot and isotopic bands are also present. The above scaling arguments are only approximate and are especially prone to error if applied to large changes in concentration where either the stronger bands may change their dependence on absorber amount, or previously unimportant weaker bands of a given gas may become relatively more important.

Increases in the concentrations of atmospheric trace gases since pre-industrial times and the consequent trapping of thermal radiation are shown in Table 2. The trapping by ozone and the CFCs, whose stronger bands are in the middle of the window region, is affected very little (~15%) by overlap with water vapour and with carbon dioxide absorption. Methane and nitrous oxide, whose strongest bands are on the short wavelength edge of the window region, lose about half of their trapping[20] by such overlap. Since much of the effect of increases in the trace gases is to make the atmospheric window region more opaque, this trapping might be called the 'dirty window' effect.

Table 2 Estimated pre-industrial trace gas concentrations and implied change in thermal trapping to 1985

Gas	Pre-industrial concentration	$\Delta Q_{\text{pre-industrial}}$ (W m^{-2})
Carbon dioxide	275 p.p.m.	1.3
Methane	0.7 p.p.m.	0.6
Tropospheric ozone (below 9 km)	0–25% less	0.0–0.2
Nitrous oxide	285 p.p.b.	0.05
CFC-11	0.00 p.p.b.	0.06
CFC-12	0.00 p.p.b.	0.12
Total		~2.2

Trapping is inferred from refs 19 and 20, scaling approximately logarithmically, with CO_2 concentration, with the square root of N_2O and CH_4 concentration, and linearly with O_3 and CFC-11 and -12 concentrations.

Atmospheric trace gases

Carbon dioxide: Atmospheric carbon dioxide concentrations are now ~25% higher than they were 200 yr ago before the age of extensive industrialization and forest clearing. Current concentrations (1985) are about 345 p.p.m. (parts per 10^6) and are increasing by 1–1.5 p.p.m. yr^{-1}, mostly as a result of continued burning of fossil fuel (adding ~5.2×10^{12} kg yr^{-1} of carbon) and forest removal (continuing to add about 10^{12} kg yr^{-1} of carbon)[10]. The basic features of the global carbon cycle are well known, but questions remain as to the contributions of land soils and forests and the rate of uptake of carbon by the oceans. The largest source of uncertainty in projecting future atmospheric carbon dioxide concentrations, however, lies in the future rates of fossil fuel combustion.

Halocarbons: Halogenated hydrocarbons (halocarbons) are now widely produced and widely used. These include fluorocarbons, chlorofluorocarbons, chlorocarbons and bromocarbons. Most scientific attention has focused on the potential role of chlorine and bromine atoms from these molecules as ozone-destroying catalysts in Earth's stratosphere[23-25]. Certain of these chemicals have also been recognized to be potent greenhouse gases[11,20].

The chlorofluorocarbons, often referred to popularly by their trade name of 'Freons', CCl_3F (CFC-11) and CCl_2F_2 (CFC-12), were measured first in the atmosphere in 1971 (ref. 26) and 1973 (see, for example, ref. 27), respectively. Since then, increasingly accurate and precise measurements have shown that their atmospheric concentrations have grown at about the same rate as would be expected from industrial production and release into the atmosphere[24,28], after minor corrections for the amounts produced but not yet released and for the quantities destroyed in the stratosphere and dissolved in oceans. In 1981, there were about 6.0×10^9 kg of CFC-12 in the atmosphere together with 5.0×10^9 kg of CFC-11. At 1981 release rates, these amounts represent the cumulative results of 15–20 yr of global emissions. (Unpublished data from several investigators give 1985 mixing ratios of CFC-11 of at least 0.22 p.p.b. and for CFC-12 of at least 0.38 p.p.b.). Indeed, atmospheric concentrations of these compounds were observed to have increased by ~6% yr^{-1} during 1978–81 (refs 29, 30). In the early 1970s, annual emissions were a larger fraction of the amounts already in the atmosphere, and larger percentage annual increases were observed, along with considerably more CFCs in the Northern Hemisphere than in the Southern Hemisphere. Although most of the release continues to be in the Northern Hemisphere, the hemispheric difference has decreased to <10%.

A projection of concentrations of atmospheric CFC-11 and CFC-12 beyond the present requires some knowledge about future industrial production and release rates. Current releases annually increase mixing ratios of CFC-11 by about 12 p.p.t. (parts per 10^{12}) and CFC-12 by 21 p.p.t., as estimated from changing atmospheric concentrations. A recent report[31] attempts to estimate their future production and release rates and that of several other similar chemicals; it recognizes the dynamics of changing industrial usages, competitive products and world and regional populations. Worldwide CFC-11 emissions are projected to increase by between 2.8 and 5.1% yr^{-1} from 1980 until 2000; corresponding figures for CFC-12 are 2.5–3.5% yr^{-1}. Between AD 2000 and 2025, CFC-11 emissions could change by −1% to +4.7% yr^{-1} and CFC-12 emissions would increase by between 1.0 and 4.6% yr^{-1}. Beyond the year 2025, growth estimates are less well-based, but Quinn *et al.*[31] suggest annual increases of 0.6–2.0% for CFC-11 and 1.1–2.1% yr^{-1} for CFC-12.

Even if future release rates of CFC-11 and CFC-12 remained at present levels, their atmospheric concentrations would continue to increase for the next century because of the relatively long residence times, τ_i, for these species, at least 60 and 100 yr, respectively[32]. In general, for a well-mixed chemical with sources $S(t)$

$$\frac{dN(t)}{dt}=S(t)-N(t)/\tau \qquad (1)$$

where $N(t)$ is the total number of molecules (or mass) of the given species in the global atmosphere at time t. Even if we were to assume that present emissions remained constant, equation (1) shows that concentrations of CFC-11 and CFC-12 would more than double, to values of ~0.5 and 1.0 p.p.b. respectively, within the next 40 yr and eventually rise to values of ~0.7 and 2.1 p.p.b., using 60- and 100-yr lifetimes, respectively.

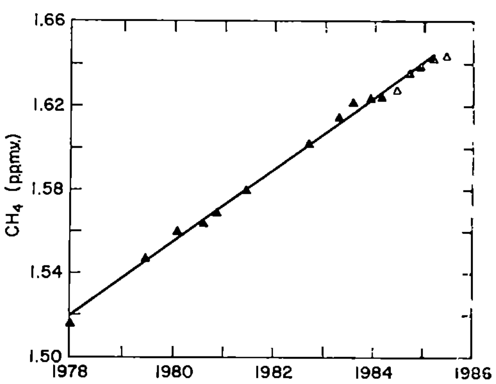

Fig. 2 Globally averaged methane concentrations in surface air from January 1978 to June 1985 as measured by Blake and Rowland[42]. Air samples were collected simultaneously from northern and southern latitudes. In computing global averages, measured values were weighted by the Earth's area in latitude belts. In 1985, there are 4.8×10^{15} g CH_4 in the atmosphere; annual sources (sinks) are $(3–7)\times10^{14}$ g.

Other halocarbons requiring attention include CCl_4, $CClF_3$, CF_4, $CHClF_2$, $CHCl_2F$, $C_2H_3Cl_3$, $C_2Cl_3F_3$, $C_2Cl_2F_4$, C_2ClF_5, C_2F_6, $CBrF_3$ and $CBrClF_2$. Because of the location of the absorption bands of these species and their rapid rates of accumulation in the atmosphere, they represent potentially important greenhouse gases. Research is needed to quantify their band absorbances and atmospheric concentrations with special attention to $CHCl_2F$ and $C_2Cl_3F_3$.

Nitrous oxide: Atmospheric N_2O is increasing in concentration globally, although the record of its past change is not as extensive as that for methane, and the reasons for this increase are less clear than those for halocarbons. Weiss[33] measured a global increase of ~0.6 p.p.b. yr^{-1} (0.2% yr^{-1}) between 1976 and 1980, whereas Khalil and Rasmussen[34] find an 0.8 p.p.b. yr^{-1} increase between 1979 and 1982. The mid-1980 N_2O concentration in the Northern Hemisphere was 301 p.p.b. and in the Southern Hemisphere it was ~0.8 p.p.b. less. Weiss fits his 1976–80 data with one of two curves; either one that assumes an added combustion source of N_2O growing at 3.5% yr^{-1} or one that assumes an agricultural-fertilizer source growing at 6% yr^{-1} (ref. 33) with an atmospheric residence time of 100 yr in both cases. Weiss, in extending his N_2O monitoring through 1984, finds that global concentrations continue to rise by 0.6 p.p.b. yr^{-1} (personal communication), but that it is not yet possible to distinguish between the two source-growth curves that fit the data. Earlier data from 1961–74 showed similar rates of N_2O increase[35].

Although the present observed and projected rates of N_2O increase may seem small, they imply that total global sources of N_2O are now elevated by ~30% over unperturbed steady-state sources, assuming a growth rate of 0.2% yr^{-1} and a 150-yr lifetime for N_2O. If the N_2O increase is due to either increased microbial nitrification and denitrification of agricultural fertilizers, or combustion, then much of this imbalance has developed in the past few decades and it may continue to grow rapidly.

Concentrations of N_2O of 320–330 p.p.b. are likely by AD 2000, regardless of which anthropogenic source is assumed to be growing[33,34]. Better future projections require determination of whether increased combustion of nitrogen-containing fuels[36,37] and biomass[21] or increased application of nitrogen fertilizers[38] is primarily responsible for the continuing N_2O increase. Both sources are difficult to quantify; field losses of N_2O due to microbial nitrification and denitrification of nitrogen fertilizers are variable[38,39] and candidate elementary reactions

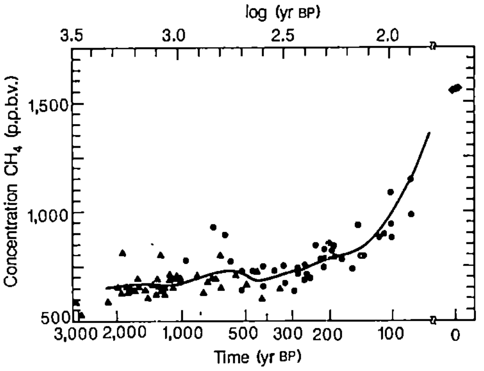

Fig. 3 Concentrations of atmospheric methane (100-300 yr BP) from ref. 44. ●, Data from polar ice cores obtained from Greenland; ▲, data from ice cores at the South Pole. The present concentration of methane is shown on the right (◆). The solid line is the smoothed average concentration based on the data; it is the average concentration in successive overlapping periods of 0.3 units each in the log (l) scale at the top of the figure.

that can produce N_2O in combustion have been identified only recently[40].

Methane: Methane is of considerable scientific interest because of its relatively rapid growth and the diverse possible causes of this increase. Global concentrations have increased by $>1\%$ yr^{-1} since 1978, as shown by Fig. 2, based on data from flame-ionization gas chromatography. A reanalysis[41] of ground-based solar absorption infrared spectroscopic data concludes that the concentration of tropospheric CH_4 in 1951 was 1.15 p.p.m., about 30% below that of 1985 (ref. 42). An earlier re-examination of infrared data from the 1950s and 1960s had concluded[43] that the rate of methane increase was slower.

The increase in global methane apparently began in previous centuries. Figure 3 shows an analysis of gases trapped in dated ice cores[44], indicating that methane concentrations have doubled since the eighteenth century, but that they were relatively constant for the previous 2,000-3,000 yr. Selective diffusion of CH_4 out of old ice cores may have biased the data of Fig. 3 (ref. 43), but H. B. Craig, who earlier found similar results[45], considers this unlikely (personal communication) based on his tests. Further confirmation has been reported[46]. Methane-consuming microbes may have lived in the ice, but we consider this unlikely.

Why has atmospheric methane increased in the past, and what is its future? Answering these questions requires knowledge of both the sources and sinks of methane. Ehhalt[47] summarized five measurements of ^{14}C in samples from air liquefication plants in the 1950s. These samples had a ^{14}C content of about 80% of that of standard wood, or equivalently 20% 'dead carbon' from fossil fuels. He suggested that this value of 20% should only be used as an upper limit since air liquefication plants are usually situated in heavily industrialized areas so that the samples were subject to contamination from local fossil-fuel-derived methane. Various authors over the past decade have constructed methane-source inventories subject to this constraint. A recent examination[21] lists rice paddies, ruminant animals, biomass burning, swamps and marshes, natural gas, and coal mining losses as the major sources, in decreasing order of importance. However, serious questions of mechanisms and related ecological variability remain[48-51]. Further, we should be cautious about conclusions drawn from the 1950s ^{14}C data because: first, the relative sizes of ^{14}C-rich and ^{14}C-poor sources are probably changing with time; and second, the old samples, collected by liquefying air, may not be representative of the $^{14}CH_4/^{12}CH_4$ in air. Unfortunately, few conclusions can be drawn about methane sources from ^{14}C analyses today in view of the bomb-produced ^{14}C in the contemporary biota and sediments. It might be useful to examine the concentrations of the ^{13}C stable isotope; such research is just beginning[52].

The principal known sink of atmospheric methane is the gas-phase reaction $OH + CH_4 \rightarrow CH_3 + H_2O$ (ref. 72). Some tantalizing but indirect evidence suggests that atmospheric OH concentrations are decreasing[53], at least in NO poor regions—the lower and middle troposphere; increasing methane and increasing CO concentrations (not yet proven) should act to suppress OH (ref. 54) through nonlinear atmospheric chemistry.

Ozone: Ozone is of considerable interest because of its important roles, its complex behaviour, and its susceptibility to human-induced global change. Near the ground in urban areas, ozone is a pollutant. Throughout the global troposphere, ozone photolysis initiates free-radical chemistry. In the middle and upper stratosphere, where the largest concentrations are found, ozone strongly attenuates solar ultraviolet light and in doing so drives stratospheric wind systems.

Tropospheric ozone increases are difficult to discern with extant observing systems, but increases have been indicated. A recent critical analysis[55] of ozone data finds that, on average over Europe and North America from the late 1960s to the early 1980s, near-surface ozone has increased by 1-3% yr^{-1} and ozone in the middle troposphere (700-500 mbar) by 1-2% yr^{-1}. These increases occur largely during the summer, especially in industrialized areas. Such increases might have begun in the 1940s, as is suggested by shifts in the seasonal cycle of ozone concentrations and other scattered observations[55]. There is considerable variability and little evidence for change in the upper troposphere.

Theoretical models of tropospheric chemistry predict that increasing anthropogenic releases of hydrocarbon and nitrogen oxide (NO_x) gases should be increasing tropospheric ozone[55-57,15]. Such increases depend on poorly known atmospheric NO_x concentrations and on some meteorological processes such as vertical transport and chemical roles of clouds, but changes in the Northern Hemisphere should be larger than those in the Southern Hemisphere, as is evidently observed. Future changes in the stratosphere may also lead to increases of tropospheric ozone.

As discussed previously[20], most studies of the latitudinal variation of tropospheric ozone indicate that concentrations in the Northern Hemisphere are at least 50% higher than in the Southern Hemisphere. However, a recent aircraft survey has given contradictory results[58], possibly because of seasonal or longitudinal variations. Furthermore, latitudinal variations may be due to transport[59].

An association of observed trends of ozone in the Northern Hemisphere with increases in total fossil fuel use would also support the possibility of an increase of tropospheric ozone in the Northern Hemisphere of up to 50% over pre-industrial values. We indicate in Table 2 that global average tropospheric ozone (below 9 km) is estimated to have increased by between 0 and 25% since pre-industrial time. Improving estimates of past or future ozone change will require a better understanding of the contributions of ground and high-level pollution.

Global stratospheric ozone changes are likely to occur because of continuing and accelerating human activities[24,25]. Increasing concentrations of chlorofluorocarbons and nitrous oxide decrease stratospheric O_3 at altitudes above 30 km. Changes of ozone in the lower stratosphere are more complex and difficult to project; they will depend on latitude and altitude and on wind systems[59,60]. A variety of chemical reactions involving polyatomic species (many of which have yet to be measured in the atmosphere) also affect this response.

Future scenarios

For comparing the future climate effects of the various trace gases, we take the year 2050 as a reference point and assume the ranges indicated in Table 3. The question of possible future concentrations for CO_2 has been extensively studied, and we have adopted values from the latest such study[10].

A range of possible future emissions for CFC-11 and CFC-12 has been obtained from economic analysis[31], and we have used these emissions together with equation (1) to obtain the concentrations shown in Fig. 4. Concentration scenarios have taken $\tau = 60$ yr for CFC-11 and $\tau = 100$ yr for CFC-12, near the low end of most previously inferred values[32]. Lifetimes are likely to lie in the range 50–80 yr and 90–130 yr, respectively. These lifetimes will decrease in the future, as increased concentrations of chlorine atoms lower the ozone concentrations above 30 km, and hence increase the fluxes of ultraviolet that photolyse the CFCs. Obvious decreases in the total column ozone following stratospheric ozone decrease are likely to trigger political constraints on further increases in the production of the CFCs. Our projections neglect the uncertainty in CFC lifetimes and their decrease with increasing burden and also neglect possible emission reductions from future regulation of CFC production.

Table 2 shows that the radiative effect of the CFCs which have been added to the atmosphere up to 1985 is only ~11% of that from CO_2 increases. However, the CO_2 increase has occurred over the past two centuries, and the current burden of CFCs has been added almost entirely within the past 30 yr. The radiative effect of these CFCs added over the past 30 yr is about one-third that of the CO_2 added over the same period. Table 3 indicates that for the assumed future scenario the additional radiative trapping by the CFCs between 1985 and 2050 is likely to be ~70% that of CO_2. This increase in the relative importance of the CFCs in the future follows from the near-linear dependence on concentration of the CFC radiative effects versus the logarithmic dependence of the effects of CO_2.

Because of our current relatively poor understanding of the reasons for the increases in methane concentrations, a wide range of possible futures appears in Table 3. A continuation of the current growth rate of 1.2% yr^{-1} to the year 2050, assuming present methane lifetimes, would give 3.7 p.p.m. at that time. Increases in methane will probably be amplified by decreasing OH, but will be diminished by slowdown in population growth and required resources. Another recent analysis[21] argues that increases from pre-industrial concentrations are likely to be proportional to projected future populations. They accordingly infer concentrations of 2.5 p.p.m. by 2050; values this small would require a large reduction in methane growth rates within the next few decades. We judge that in the year 2050 concentrations will lie between 2.1 and 4.0 p.p.m. The upper limit is inferred from the extrapolation of current growth plus a small decrease (8%) of methane lifetimes. Methane lifetimes may decrease by much more[54]. The lower limit is inferred by arguing that the current trend should last at least 20 yr but that, considering our ignorance of the processes involved, we cannot exclude absence of further growth after that. Table 3 suggests that from now to 2050 the radiative effects of increasing methane are likely to be about one-quarter that of CO_2. Table 2 indicates that the increase in radiative trapping from past methane increases has been about the same as that expected from future methane increases and is about half of that inferred from past CO_2 increases. Methane has already increased to ~250% of pre-industrial values and probably will not repeat this relative increase by 2050. The relative increase of CO_2, on the other hand, will probably be greater in the next 65 yr than it has been up to now[10].

If the anthropogenic source of nitrous oxide were to continue to grow at 3.5% yr^{-1}, it would increase by a factor of 10 by the year 2050 and N_2O concentrations would rise above 500 p.p.b. (ref. 33). Such rapid future growth is probably excluded by economic and population constraints[21]. Assuming that a quadrupling of the current emission rates over the next 65 yr is not impossible, we infer an upper limit for N_2O concentrations of 450 p.p.b. for the year 2050. We infer a lower limit of 350 p.p.b. for the year 2050 using an average annual increase similar to that now observed.

A likely upper limit to fossil-fuel consumption over the next century is about four times current consumption rates[10]. With such consumption and an upper limit of 20% of current ozone associated with fossil-fuel pollution, global tropospheric ozone could conceivably increase by 60% over current values. Ozone will also increase in the upper troposphere and lower stratosphere in response to increases of the CFCs and to oxides of nitrogen from increasing jet aircraft traffic. The details of latitudinal and especially vertical distribution of ozone change are important for any accurate estimate of climate effects. Lacking such details, we estimate the likely radiative trapping of changing ozone concentrations by the year 2050 as that given by a change in ozone between 0 and 50% uniformly over the altitude range 0–12 km.

To determine the net contribution to radiative trapping included in Table 3, we have simply summed separately the upper and lower limits of the projected contributions of the individual gases. Although all contributions are unlikely to achieve their upper or lower limits simultaneously, this assumption probably does not overestimate the likely range of total trapping for two reasons. First, the rates of increase of the different trace gases are more likely to be highly correlated than not—their sources all depend heavily on fossil-fuel utilization; methane and nitrous oxide emissions both also depend on agricultural development and that of the CFCs on general technological development. Second, past experience with similar uncertain environmental questions indicates that actual uncertainties are likely to be larger than can be judged from simple arguments such as those used here. In particular, there are many other trace gases present in small but rapidly growing concentrations[20], some of which will add significantly to global warming by the year 2050.

Table 3 Scenario for trace gas concentrations in the year 2050 and implied increased trapping of thermal radiation from 1985 (ref. 19)

Gas	Year 2050 scenario	ΔQ_{2050} ($W\,m^{-2}$)
Carbon dioxide	400–600 p.p.m.	0.9–3.2
Methane	2.1–4.0 p.p.m.	0.2–0.9
Tropospheric ozone (0–12 km)	15–50% more	0.2–0.6
Nitrous oxide	350–450 p.p.b.	0.1–0.3
CFC-11	0.7–3.0 p.p.b.	0.23–0.7
CFC-12	2.0–4.8 p.p.b.	0.6–1.4
Total		2.2–7.2

Referring to either the lower or the upper limit totals in Table 3, we infer that the total contribution of the other trace gases is more likely than not to exceed the contribution from CO_2.

Implications for climate change

We have aimed to provide an overall framework for considering the relative contributions of various trace gases to climate change. Relatively realistic three-dimensional climate models have been used to study only a very limited number of scenarios for future climate; that is, scenarios assuming a steady-state doubling or quadrupling of atmospheric carbon dioxide concentrations. The radiative forcing for the latter is about double that for the former.

The future climate change from likely increases of all trace gases will undoubtedly differ in detail from that inferred from the superposition of the climate changes that would occur, assuming that each trace gas changes separately. Furthermore, the climate change from individual trace gases depends not only on the global average trapping of radiation as discussed here, but also on the latitudinal and especially vertical distributions of atmospheric heating or cooling changes implied by the trace gas change. However, the implications of these details have not yet been satisfactorily resolved, and so our estimates of the climate change resulting from the various trace gases assume that the dependence of this climate change on external forcing can simply be represented by the global radiative trapping alone.

Indeed, the radiative trapping values given in Tables 1-3 are only approximate estimates. Their precise values depend not only on (somewhat uncertain) band strengths but also on the temporally and spatially varying distributions of cloudiness and atmospheric temperatures. The values used here have been inferred mostly from simple one-dimensional models of the atmosphere. Recognizing these caveats, we suggest that at present the most useful way to estimate the future climate change from CO_2 and the other trace gases is to scale from the studies that have been done on climate change from CO_2 increases, allowing for the time lag required for the oceans to warm up.

Three-dimensional general circulation models (GCMs) represent the climate system as the sum of the day-to-day weather systems integrated over many years of simulated time. In doing so, they can include realistically all the feedbacks of simpler models plus those that depend on the details they generate. They include, in particular, albedo feedbacks from seasonally varying snow and sea ice, lapse rate feedbacks involving adjustment to moist adiabatic lapse rates in tropical latitudes, controls by baroclinic disturbances in mid-latitudes, and feedbacks by the highly stable stratification of polar latitudes. Cloud feedbacks are potentially very important for amplifying global temperature change, but they cannot be inferred yet with confidence, and negative feedbacks on solar radiation absorption from changes in cloud liquid water have not been included[61].

Because of the difficulty in isolating individual feedbacks in GCMs, and the expense of examining all trace gases of possible significance, simpler energy balance[62] and convective adjustment models[63] have also proved valuable.

Recent GCM simulations[3,6,7] give for steady-state CO_2 doubling ($\Delta Q \simeq 4.0\ \mathrm{W\,m^{-2}}$) a global average temperature increase of between 2.1 °C (ref. 3) and 4.8 °C (ref. 6). Consideration of uncertain model feedbacks suggests that a value as low as 1.5 °C or as high as 5.5 °C is possible[10].

Because several decades or more are required for the oceans to equilibrate with changes in global radiation[64-69], we cannot convert the heating rates given in Tables 2 and 3 directly into expected temperature changes for the same dates. However, continuing the current burden of trace gases added by human activities indefinitely implies an eventual increase from pre-industrial temperatures of 0.5-2° C. Global mean temperatures can only be estimated with any confidence back to 1900. About two-thirds of the anthropogenic forcing has developed since that time. Oceanic thermal inertia is currently reducing the temperature response by (very roughly) half of what it would be in a steady state. Allowing for this factor, we infer a temperature increase of 0.3-1.0 °C from 1900 to the present[10,70]. The observed increase is about 0.5 °C (refs 10, 70) which would seem to confirm the present analysis. However, global temperatures around 1940 were nearly as warm as now and they declined in the 1960s. Thus, unexplained climate variations occur that will probably confound unambiguous identification of the trace gas signal for at least another decade or two.

The scenarios given in Table 3 imply that by the year 2050 there will be a global average temperature increase of 1 °C to >5 °C, depending on the extent of positive feedbacks in the climate system and on reduction of the response by oceanic heat uptake. Global temperatures will probably continue to grow well into the twenty-second century as the atmospheric loading of trace gases and ocean heat content increases further.

The GCMs simulate not only global conditions but also the detailed geographical distribution of many climate parameters including the atmospheric hydrological cycle. Implications of future climate change from trace gases for agriculture and natural ecosystems require establishing these details with some confidence. All the GCM simulations indicate largest temperature changes in high latitudes. Some models strongly suggest a significant mid-latitude, mid-continent summer drying. Past model studies have inspired a wide range of climate-impact 'what if' studies, examining the potential implications of the range of possible future climates[73]. However, practical analyse will require a new generation of climate models whose globa feedbacks and regional simulations can be accepted wit confidence. They will also require allowance for the large-scal adjustments of human systems that can occur on the timescale involved[71].

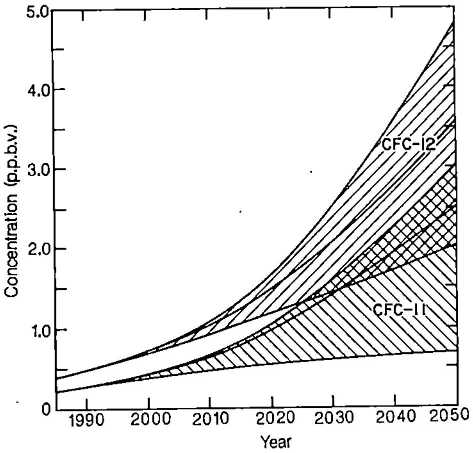

Fig. 4 Range of possible scenarios of the concentrations of CFC-11 and CFC-12 between 1985 and 2050 as inferred from future sources projected from an economic analysis[31]. Upper, lower and middle scenarios are shown for each gas and their ranges are indicated by the slanted line patterns.

Accurate model predictions may take more than a decade t arrive. Meanwhile, further emphasis should be given to definin and bounding the uncertainties in future climate change[7 Without a better understanding of the extreme upper limits t possible future climate change, we must view with considerabl concern this global experiment now under way.

Masses of the satellites of Uranus

S. F. Dermott & P. D. Nicholson

Center for Radiophysics and Space Research, Space Sciences Building, Cornell University, Ithaca, New York 14853, USA

The dynamical theory used to obtain the masses of the uranian satellites from their orbital precession rates contains a fundamental error. The masses can be derived from the precession rates, but a correct analysis of the available data must allow for the fact that the eccentricities, inclinations and precession rates all vary considerably with time, due to mutual secular perturbations.

THE Voyager 2 spacecraft should encounter Uranus on 24 January 1986 and we will then obtain the first detailed images of this puzzling and poorly understood system. Visual observations by Sir William Herschel in 1781 and Lassel in 1851 revealed the presence of four major satellites of similar size: Ariel, Umbriel, Titania and Oberon[1]. The comparatively small and innermost satellite, Miranda, was discovered photographically by Kuiper in 1948 (ref. 1). All of these satellites orbit the planet in direct, near-equatorial, near-circular orbits, but the dynamics of the system appear to be quite different from those of the satellite systems of Jupiter and Saturn. This difference has been insufficiently recognized, which has led to serious misinterpretations of the available observational information.

The radii and the masses of the satellites are presented in Table 1. Brown *et al.*[2] and Brown and Clark[3] determined the satellite radii from photometric and radiometric measurements using a version of the standard radiometric model developed for asteroids. The latest and most complete derivation of the satellites' orbital elements (Table 2) is due to Veillet[4], who has also determined the masses of the four larger satellites from the observed pericentre precession rates[5,6]. The striking feature of these results is the marked dichotomy in the derived satellite densities; the densities of Ariel and Umbriel are similar to those of the inner satellites of Saturn, and are consistent with a composition of 40% rock and 60% water-ice, but Titania and Oberon appear to have much higher densities, suggesting that the water-ice constitutes little more than a thin outer shell. Near-infrared reflectance spectra show that all five satellites have surfaces of water-ice contaminated with a dark spectrally neutral material showing spectral characteristics similar to those of, for example, carbonaceous chondritic material[7].

Table 1 Masses of the uranian satellites

j	Satellite	Radius* (km)	m/M† $\times 10^5$	m/M‡ $\times 10^5$	Densities§ (g cm^{-3})
1	Miranda	250±110	~0.1	0.2±0.2	—
2	Ariel	665±65	1.8±0.6	1.8±0.4	1.3±0.5
3	Umbriel	555±50	1.1±0.3	1.2±0.5	1.4±0.6
4	Titania	800±60	3.2±0.8	6.8±0.8	2.7±0.6
5	Oberon	815±70	3.4±1.0	6.9±0.8	2.6±0.6

* From ref. 2.

† Derived from the radii of Brown *et al.*[2] using a nominal density of .3 g cm^{-3}. The quoted uncertainties in the masses take no account of he uncertainties in the densities.

‡ From ref. 4.

§ Derived from the radii of Brown *et al.*[2] and the masses of Veillet.

A second unusual feature of the Uranus system is the fact that all five satellites have comparable non-zero orbital eccentricities. Since the prediction[8] and discovery[9] of active volcanism on Jupiter's satellite Io, it has been realized that tidal heating due to eccentricity damping may dominate the internal heat budgets of some satellites, so that the thermal evolution of some satellites cannot be understood without a concomitant understanding of their orbital evolution. This is certainly true for Io and may also be for Europa[10-12] and for the saturnian satellite Enceladus[13]. The observed orbital eccentricities and the calculated tidal damping timescales of the uranian satellites are shown in Table 2. It is puzzling that the inner satellites have tidal damping timescales much shorter than those of the outer satellites, probably much shorter than the age of the Solar System, even though all the orbital eccentricities are both finite and of similar magnitude[14,15].

We argue here that the problem posed by the satellite density distribution arises from a misunderstanding of the orbital dynamics and may be imaginary. We also show that the observed eccentricities of the inner satellites, Miranda and Ariel, may be partly forced by the outer satellites and that these forced eccentricities may be maintained despite strong tidal damping.

Secular perturbations

In the jovian and saturnian systems, the orbital elements of many of the satellites (Io, Europa and Ganymede; Mimas, Enceladus, Tethys, Dione and Hyperion) are affected by orbit-orbit resonances. With the exception of a near-commensurability involving Miranda, Ariel and Umbriel, the Uranus system exhibits no true resonances of this type. In the absence of such resonant interactions, the long-term variations in the orbital eccentricity, e, and the inclination, I, of a satellite are largely determined by the secular terms in the satellite's disturbing function, that is, by those terms in the disturbing function that do not depend on the mean longitudes of any of the satellites. If we number the satellites from 1 to n in order of increasing semimajor axis, a, then the secular part of the truncated disturbing function, R_j, for the jth satellite can be written[16]

$$R_j = n_j a_j^2\left[\frac{1}{2}A_{jj}e_j^2 + \sum_{\substack{k=1\\k\neq j}}^{n} A_{jk}e_je_k\cos(\tilde{\omega}_j-\tilde{\omega}_k)\right.$$
$$\left.+\frac{1}{2}B_{jj}I_j^2+\sum_{\substack{k=1\\k\neq j}}^{n} B_{jk}I_jI_k\cos(\Omega_j-\Omega_k)\right] \tag{1}$$

where

$$A_{jj} = n_j\left[\frac{3}{2}J_2\left(\frac{R_p}{a_j}\right)^2-\frac{9}{8}J_2^2\left(\frac{R_p}{a_j}\right)^4-\frac{15}{4}J_4\left(\frac{R_p}{a_j}\right)^4\right.$$
$$\left.+\frac{1}{4}\sum_{\substack{k=1\\k\neq j}}^{n}\frac{m_k}{M}\alpha_{jk}\bar{\alpha}_{jk}b_{3/2}^{(1)}(\alpha_{jk})\right] \tag{2}$$

$$B_{ij} = -n_j\left[\frac{3}{2}J_2\left(\frac{R_p}{a_j}\right)^2-\frac{27}{8}J_2^2\left(\frac{R_p}{a_j}\right)^4-\frac{15}{4}J_4\left(\frac{R_p}{a_j}\right)^4\right.$$
$$\left.+\frac{1}{4}\sum_{\substack{k=1\\k\neq j}}^{n}\frac{m_k}{M}\alpha_{jk}\bar{\alpha}_{jk}b_{3/2}^{(1)}(\alpha_{jk})\right] \tag{3}$$

$$A_{jk} = -\frac{1}{4}\frac{m_k}{M}n_j\alpha_{jk}\bar{\alpha}_{jk}b_{3/2}^{(2)}(\alpha_{jk}) \tag{4}$$

and

$$B_{jk} = \frac{1}{4}\frac{m_k}{M}n_j\alpha_{jk}\bar{\alpha}_{jk}b_{3/2}^{(1)}(\alpha_{jk}) \tag{5}$$

In these expressions

$$\alpha_{jk} = \begin{cases} a_k/a_j & \text{if } k<j \\ a_j/a_k & \text{if } k>j \end{cases} \tag{6}$$

$$\bar{\alpha}_{jk} = \begin{cases} 1 & \text{if } k<j \\ \alpha_{jk} & \text{if } k>j \end{cases} \tag{7}$$

n_j is the mean motion, $\tilde{\omega}_j$ is the longitude of pericentre, Ω_j is the longitude of the ascending node, and m_j is the mass, all for the jth satellite. M, R, J_2 and J_4, are, respectively, the mass, the radius and the first two zonal gravity coefficients of the planet, and the $b_s^{(k)}$ are Laplace coefficients[16]. Since J_2 is non-zero, the orbital inclinations of the satellites must be referred to the equatorial plane of the planet. In writing these expressions, we have neglected solar perturbations (negligible for the uranian satellites), terms of fourth order and higher in the satellite eccentricities and inclinations, and terms of second order in the masses.

The solution of Lagrange's equations for the orbital element variations produced by this disturbing function follows the method described by Brouwer and Clemence[16]. It is convenient to transform the conventional orbital elements into the symmetrical forms

$$\begin{aligned} h &= e\sin\tilde{\omega} \\ k &= e\cos\tilde{\omega} \end{aligned} \tag{8}$$

and

$$\begin{aligned} p &= \sin I\sin\Omega \\ q &= \sin I\cos\Omega \end{aligned} \tag{9}$$

in terms of which the solutions take the simple harmonic form:

$$\begin{matrix} h_j \\ k_j \end{matrix} = \sum_{i=1}^{n} e_{ji} \begin{matrix} \sin \\ \cos \end{matrix}\left(g_it+\beta_i\right) \tag{10}$$

and

$$\begin{matrix} p_j \\ q_j \end{matrix} = \sum_{i=1}^{n} I_{ji} \begin{matrix} \sin \\ \cos \end{matrix}\left(f_it+\gamma_i\right) \tag{11}$$

The eccentricity eigenfrequencies, g_i, are the roots of the determinant

$$\begin{vmatrix} A_{11}-g & A_{12} & \cdots & A_{1n} \\ A_{21} & A_{22}-g & \cdots & A_{2n} \\ A_{n1} & \cdot & \cdots & A_{nn}-g \end{vmatrix} = 0 \tag{12}$$

while the inclination eigenfrequencies, f_i, are the roots of a similar determinant involving the elements B_{jk}. The coefficients e_{ji} are components of the ith eigenvector of the matrix A, with corresponding eigenvalue g_i:

$$\sum_{k=1}^{n} A_{jk}e_{ki} = g_ie_{ji}, \qquad (j=1,2,\ldots,n) \tag{13}$$

Similarly, the coefficients I_{ji} $(j=1,2,\ldots,n)$ are components of the ith eigenvector of the matrix B, corresponding to the eigenvalue f_i. A complete solution of this form involves a total of $4n$ arbitrary constants—the magnitudes of the $2n$ eigenvectors, and the corresponding phases, β_i or γ_i, which, in turn, are determined by a complete set of $4n$ initial conditions (e_j, $\tilde{\omega}_j$, I_j, Ω_j; $j=1,2,\ldots,n$) at some epoch. Note that the solutions for the eccentricity/pericentre variations are completely decoupled from the inclination/node solutions, thus considerably simplifying the analysis.

There are two circumstances in which the variations of e and $\tilde{\omega}$ (or I and Ω) for a particular satellite are relatively simple. In the first of these two cases, the planetary term in equations (2) and (3), involving J_2 and J_4, are much larger than the satellite terms. Since all of the Laplace coefficients are comparable in size, it follows that the off-diagonal matrix elements A_{jk} $(k\neq j)$ are much smaller than the diagonal elements A_{jj}, so that the eigenfrequencies $g_i \simeq A_{ii}$ and the eigenvectors have only small off-diagonal components e_{ji} $(j\neq i)$. As a result, the eccentricities are essentially constant and the pericentre precession rates, $\dot{\tilde{\omega}}_j$, are equal to the eigenfrequencies g_j. This is true for all of the inner satellites of Jupiter and Saturn, except Rhea[17], because of these planets' large oblatenesses. In this case, $\dot{\tilde{\omega}}_j \simeq g_j \simeq A_{jj}$, and $\dot{\Omega}_j \simeq f_j \simeq B_{jj} \simeq -A_{jj}$, so that the nodal precession rate is equal, but of opposite sign, to the pericentre precession rate.

In the second case, the mass of one satellite (j, say) is sufficiently small that its perturbations on the other satellites may be neglected. In consequence, all off-diagonal terms in the jth column of matrix A may be set to zero, and the jth eigenfrequency is again given by $g_j = A_{jj}$ (or $f_j = B_{jj}$). The remaining $n-1$ eigenfrequencies are not, however, necessarily close to the diagonal terms. The eccentricity of satellite j is usually considered as comprising a 'free' component, of frequency g_j, and several 'forced' components, the latter being due to the perturbations by the other satellites. In situations where the free eccentricity is much larger than any of the forced components, the total eccentricity is again virtually constant and the pericentre precision rate is g_j. Examples of this case are provided by the asteroids, for which the (derived) free eccentricities and inclinations are known as 'proper' elements, and the forced components due to the planets are typically ~30% of the free components.

Neither of these two situations applies in the uranian satellite system: Uranus' J_2 is comparatively small[18], and all five satellites have similar masses. Rather, the uranian system is likely to be more closely analogous to the planetary system, for which J_2 (Sun) = 0, and in which all eccentricities and inclinations experience significant secular variations about their mean values. Large variations in e and I, and in $\tilde{\omega}$ and Ω, are to be expected for each of these satellites, on timescales of decades to centuries. A special case is Miranda, whose proximity to Uranus and relatively small mass are reminiscent of both cases discussed above, and which shows an anomalously large 'free' inclination (see Table 2).

Satellite masses

Because of the lack of orbit-orbit resonances in the uranian satellite system, the mutual gravitational perturbations of the satellites' mean longitudes are small and the satellite masses cannot be determined by methods that have proved useful for many jovian and saturnian satellites. The masses of the uranian satellites are, at present, determined from observations of the motions of their pericentres. Harris[5], Dunham[6] and, more recently, Veillet[4] assume that the forced eccentricities of the uranian satellites are negligible compared with their free eccentricities, and that the pericentre precession rates are constant and given by

$$\dot{\tilde{\omega}}_j = A_{jj} \tag{14}$$

Since all the a_j and n_j values are easily determined, the only significant unknowns in equation (14) are J_2 and the five satellite masses. Before the discovery of the narrow uranian rings, J_2 was not known with useful accuracy and thus Harris and Dunham were able to obtain only poor estimates of the satellite masses. However, the uncertainty in J_2 is now effectively negligible[18] and Veillet has used this fact and his own observational programme to derive the satellite masses from the five observed precession rates (see Tables 1, 2). For Titania and Oberon, in particular, the quoted uncertainties in the masses are smaller than 12%. In Table 2, the observed precession rates, $\dot{\tilde{\omega}}_{\rm obs}$, are also compared with those that would be produced by the planet alone, $\dot{\tilde{\omega}}_{\rm P}$. We see that the pericentre rates of Oberon, Titania and even Umbriel are largely determined by the mutual perturbations.

Since the coefficients $b_{3/2}^{(1)}$ and $b_{3/2}^{(2)}$ in equations (2-5) have comparable magnitudes, it follows that if the satellite masses are sufficient to increase significantly $\dot{\tilde{\omega}}_{\rm obs}$ above $\dot{\tilde{\omega}}_{\rm p}$, then the off-diagonal terms, A_{jk} and B_{jk}, must make significant contributions to the eigenfrequencies, thus rendering equation (14) inapplicable. It also follows that, if the initial eccentricities of the satellites have comparable magnitudes, then the forced eccentricities are not negligible and e_j and $\tilde{\omega}_j$ must suffer significant periodic variations. Such variations have been neglected in all published analyses of the observational data although their potential importance was mentioned by Greenberg in 1975 (ref. 17).

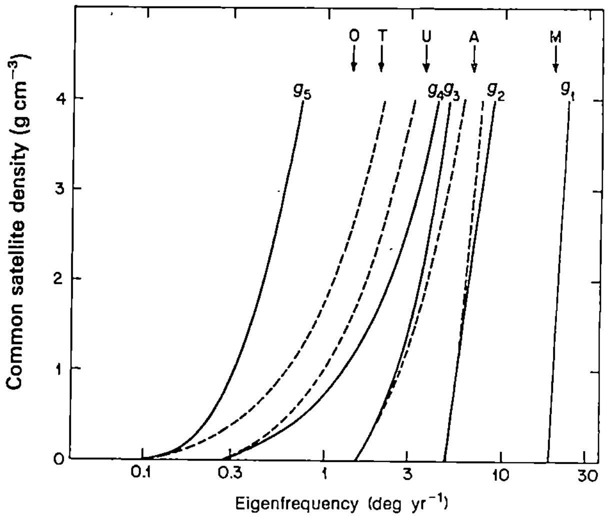

Fig. 1 The solid lines show the variations of the eccentricity eigenfrequencies with the common density of the Uranian satellites. The broken lines are the frequencies associated with the principal diagonal terms of the eigenfrequency matrix. M, A, U, T, and O denote the pericentre precession rates observed by Veillet[4] for, respectively, Miranda, Ariel, Umbriel, Titania and Oberon.

To illustrate the above statements, we consider an heuristic model in which the satellites have a common density ρ. If the off-diagonal terms, A_{jk}, in equation (12) are arbitrarily set to zero, then the forced eccentricities are also zero and the eigenfrequencies are given by the terms, A_{jj}, on the principal diagonal. Figure 1 shows these frequencies as a function of increasing density ρ (the dashed curves) compared with actual eigenfrequencies obtained by solving the full equation (the solid curves). The numbering of the five eigenmodes is chosen so that $g_i \rightarrow A_{ii}$ as $\rho \rightarrow 0$. For the first three modes, the true eigenfrequencies differ only slightly from the dashed curves for all plausible densities. The remaining two eigenmodes, however, which largely reflect interactions between the outer satellites, Titania and Oberon, deviate significantly from the dashed curves for densities as small as 0.5 g cm^{-3}. It is clear then that, at least for these two satellites, equation (14) must be seriously in error.

Table 2 Orbital elements, precession rates and eccentricity damping timescales

j	Satellite	a* (km)	e	$\tilde{\omega}_0$† (deg)	I (deg)	Ω_0† (deg)	$\dot{\tilde{\omega}}_{\rm obs}$ (deg yr^{-1})	$\dot{\tilde{\omega}}_{\rm P}$* (deg yr^{-1})	T_e/Q‡ (Myr)

* Calculated from the observed orbital periods, with $GM = 5.784184 \times 10^6$ km^3 s^{-2}, $J_2 = 3.3450 \times 10^{-3}$, $J_4 = -3.21 \times 10^{-5}$ and $R_p = 26{,}200$ km (ref. 18). Note that the published value of J_2 has been adjusted to Veillet's determination of $M_\odot/M = 22{,}945$.

† At epoch 0 January 1950, 12 h UT. e, I, $\tilde{\omega}_0$, Ω_0 and the observed precession rates, $\dot{\tilde{\omega}}_{\rm obs}$, are from ref. 4.

‡ The calculated tidal damping timescales, T_e, assume that the satellites are icy and have rigidities of 4×10^{10} dyn cm^{-2} and densities of 1.3 g cm^{-3}. Q is the tidal dissipation function and probably has a value ~10^2 (ref. 26).

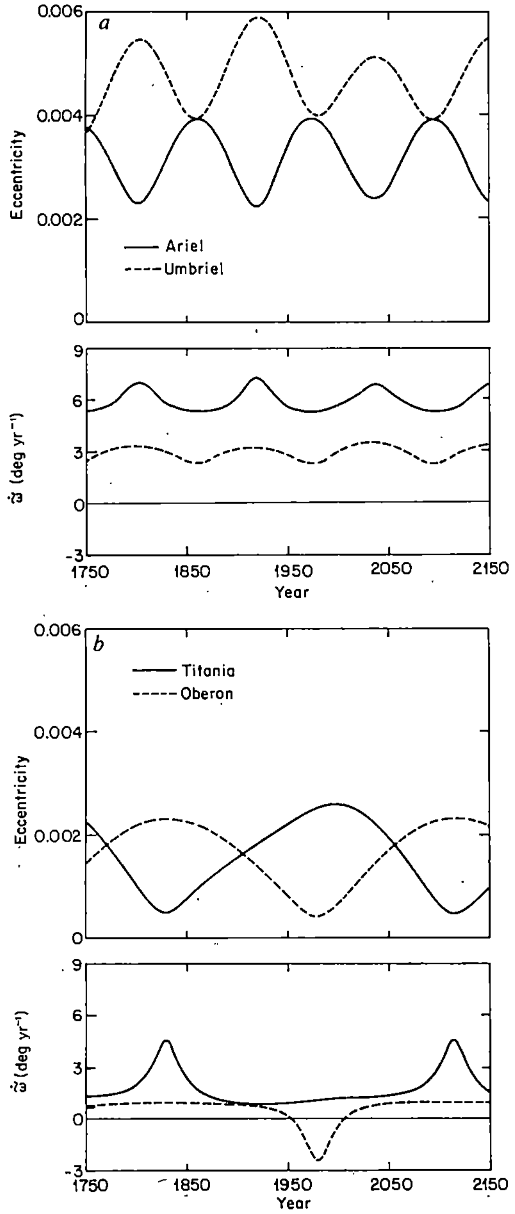

Fig. 2 Possible variations of the eccentricities and the pericentre precession rates of Ariel and Umbriel (*a*) and Titania and Oberon (*b*). We assume that the uranian satellites have a common density of 1.3 g cm^{-3}. The initial conditions are the orbital elements listed by Veillet[4] for the epoch 1950.0 (see Table 2).

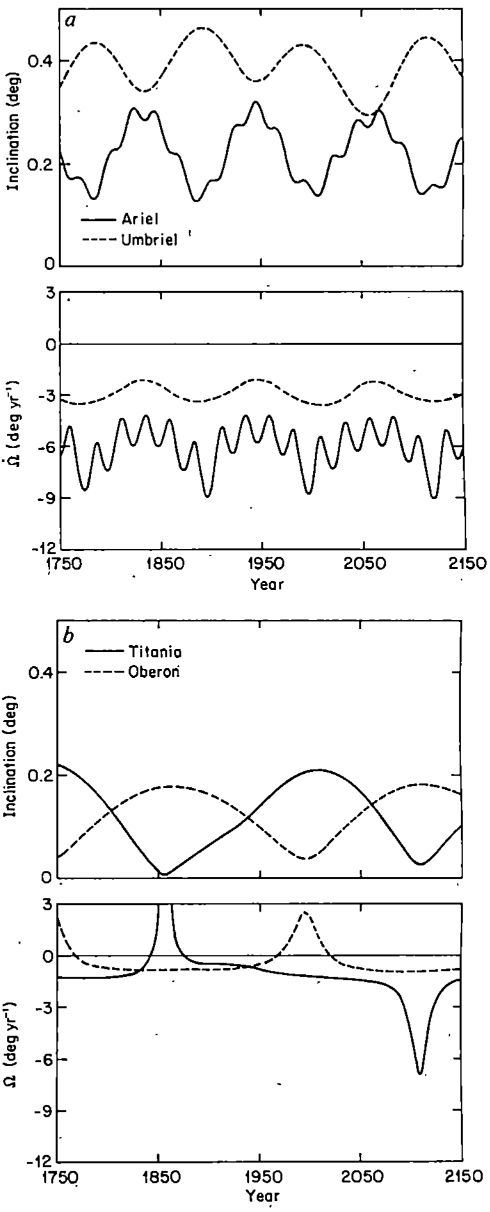

Fig. 3 Possible variations of the inclinations and the nodal precession rates of Ariel and Umbriel (*a*) and Titania and Oberon (*b*). We assume that the uranian satellites have a common density of 1.3 g cm^{-3}. The initial conditions are the orbital elements listed by Veillet[4], for the epoch 1950.0 (see Table 2).

Using masses for a nominal common satellite density of 1.3 g cm^{-3} (see Table 1), we have also calculated the normalized eccentricity and inclination eigenvectors shown in Table 3. These quantities together with the orbital elements determined by Veillet for epoch 1950.0 (see Table 2), which we use as a set of initial conditions, enable us to determine the amplitudes and the phases of the 10 eigenmodes and hence the variations of the orbital elements with time. Our results are shown in Figs 2–4. These should not be taken literally as representing 'the' variation of the uranian satellites' orbital elements, but rather as a typical example of many possible solutions. Not only is our assumption of a uniform density of 1.3 g cm^{-3} completely arbitrary (although plausible), but Veillet's elements were derived on the incorrect assumption that e and I are independent of time.

In all of these calculations, we have used the best values currently available[18] for Uranus' J_2 and J_4, adjusted to Veillet's determination of M. The semimajor axes of the satellites were re-calculated from the observed orbital periods, using the same values for M, J_2, and J_4.

Density of Ariel

Veillet[4] reports that the orbital inclination of Miranda is 4.22° ± 0.16°, in good agreement with the value of 4.0° ± 0.3° obtained by Greenberg and Whitaker[19,20]. The forced inclination components are negligible compared with this anomalously high value and Ω is, therefore, effectively constant, as shown in Fig. 4. This fact, combined with the near-equality of f_1 and B_{11} (compare with g_1 in Fig. 1), implies that the difference between the observed value of Miranda's nodal precession rate, $\dot{\Omega}_1$, and that due to the planetary oblateness alone, $\dot{\Omega}_P$ is related to the masses of the other satellites by

$$\dot{\Omega}_1 - \dot{\Omega}_P \simeq f_1 - \dot{\Omega}_P \simeq -\frac{1}{4} n_1 \sum_{k=2}^{5} \frac{m_k}{M} \alpha_{jk}\bar{\alpha}_{jk} b_{3/2}^{(1)}(\alpha_{jk}) \qquad (15)$$

Using the radii of Brown[2,3] and assuming that the four satellites ave a common density, ρ_A g cm^{-3}, this difference can be written

$$\dot{\Omega}_1 - \dot{\Omega}_p = -1.20\,\rho_A \text{ deg yr}^{-1} \qquad (16)$$

ince Ariel accounts for ~80% of the above nodal rate ifference, ρ_A is effectively the density of Ariel. $\dot{\Omega}_P = -18.99$ deg yr^{-1}, allowing for Miranda's inclination of 4.2° (ref.). If $\dot{\Omega}_1 = -19.76 \pm 0.22$ deg yr^{-1}, as reported by Veillet[4], then, llowing for the uncertainties in the satellite radii, we obtain:

$$\rho_A = 0.64 \pm 0.26 \text{ g cm}^{-3} \qquad (17)$$

his value is quite different from that calculated by Veillet[21], argely because he used an inappropriate value for the radius f Uranus (it is only the product R^2J_2 that is accurately known rom studies of the rings). If the densities of the outer satellites re greater than that of Ariel, or if unseen satellites of significant ass exist anywhere in the uranian system, then the density of riel must be even less than the remarkably low value given bove. This low density is inconsistent with that of a satellite ith a composition of rock and water-ice.

Greenberg and Whitaker[19], on the other hand, obtained a odal precession rate for Miranda of -21.6 ± 0.7 deg yr^{-1}, implyng a value for ρ_A of 2.2 ± 0.9 g cm^{-3}. These apparently inconistent results are disturbing, given the expected constancy of $_1$ and $\dot{\Omega}_1$, but the greatly enlarged data set used by Veillet hould lead to his value being preferred at present. At any rate, t is apparent that an accurate future determination of Miranda's odal precession rate would yield an important constraint on riel's density.

orced eccentricities

idal dissipation due to the tide raised by a planet on a satellite ends to circularize the satellite's orbit, while heating the satellite[8]. In the absence of eccentricity forcing, the orbital eccentricities of Miranda and Ariel would probably decay on timesales significantly less than the age of the Solar System (see able 2). Secular perturbations, on the other hand, result in an xchange of angular momentum between the inner and outer atellites on much shorter timescales (10–1,000 yr), and are thus ikely to considerably extend the eccentricity-decay times calcuated in Table 2. Essentially, the process of tidal dissipation ust now be thought of as damping entire eigenmodes, rather han individual satellite eccentricities. Naturally, those modes hich have their largest amplitudes for the inner satellites, that s modes 1 and 2 in Table 3*a*, will be damped most rapidly, hile modes 4 and 5, involving principally Titania and Oberon, ill be damped much more slowly.

An examination of the observed eccentricities of Miranda and riel, however, suggests that even modes 1 and 2 have not yet een completely damped. Based on the eigenmode solution in able 3, we find the 'forced' component of Miranda's eccentricity (due principally to Ariel) to be ~0.0003, or only about 0% of the observed value, while the forced component of riel's eccentricity (due principally to Umbriel) is ≈0.0008, ~25% of the observed value. (The term 'forced' is used loosely o refer to that component of the eccentricity which is not due o the eigenmode most closely associated with the satellite in uestion). This conclusion is supported by the observation that iranda and Ariel exhibit pericentre precession rates close to he calculated eigenfrequencies for modes 1 and 2, respectively see Tables 2, 3 and Fig. 1).

Thus, we cannot account for the observed eccentricities of iranda and Ariel purely in terms of forcing by the outer atellites. However, since Veillet's observational data need to e re-reduced in the light of our findings on the variability of e orbital elements, the latter conclusion may be premature. e note that the osculating elements of Miranda obtained by eillet from data taken on eight nearly consecutive nights in pril 1981 give an eccentricity of 0.0007 ± 0.0004 (ref. 21). This w value is consistent with what we would expect if tidal dissipation had entirely damped out the first eccentricity eigenmode, but not the second.

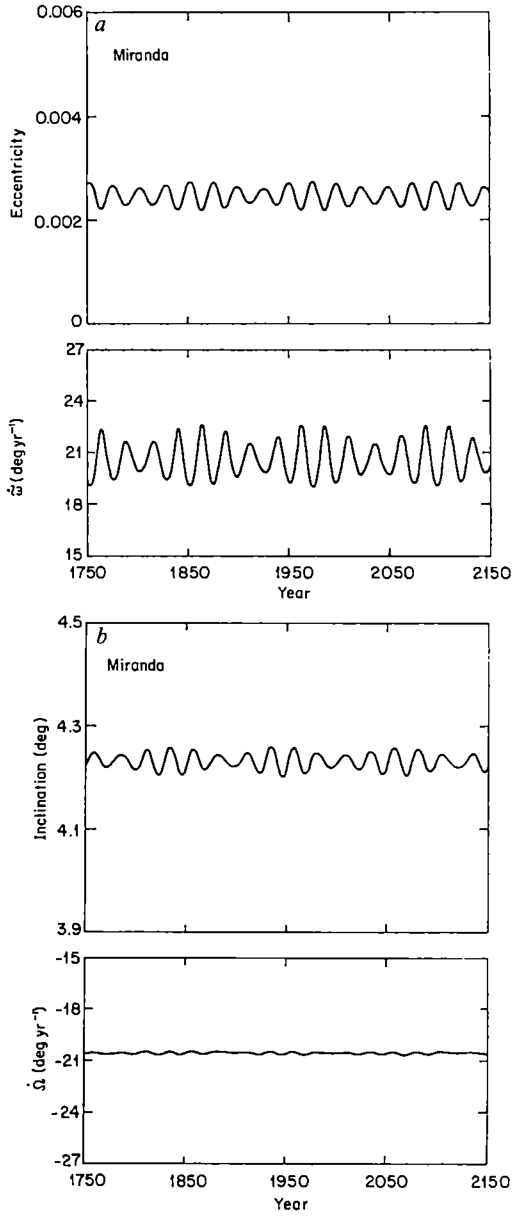

Fig. 4 Possible variations of the eccentricity (*a*) and the inclination (*b*) of Miranda and the corresponding variations in the precession rates, $\dot{\tilde{\omega}}$ and $\dot{\Omega}$. We assume that the uranian satellites have a common density of 1.3 g cm^{-3}. The initial conditions are the orbital elements listed by Veillet[4] for the epoch 1950.0 (see Table 2).

If the large amplitudes of the first two eigenmodes are confirmed by subsequent studies, then maintenance mechanisms outside those provided by low-order secular perturbation theory must be sought. Perturbation terms of second-order in the masses will produce variations in e and I on timescales $\Gamma \sim T/(m/M)^2$, where T is the characteristic orbital period. For the uranian satellites, $\Gamma \sim 10^8$ yr. If Γ is less than the eccentricity damping timescales, it is conceivable that these second-order perturbations may result in an exchange of angular momentum between the inner and the outer satellites sufficient to maintain the eccentricities of the inner satellites. This possibility will be investigated in the near future, by means of very long-term numerical integrations of test satellite systems (A. Milani and A. M. Nobili, personal communication). Another possibility is that an expansion of the orbits of Miranda and Ariel due to tidal dissipation in the planet has resulted in the comparatively

Table 3 Eccentricity and inclination eigenvectors for a common satellite density of 1.3 g cm^{-3}

a Normalized eccentricity eigenvectors

recent passage of these satellites through orbit-orbit resonances[14]. Passage through resonance may have resulted in the excitation of both a high eccentricity and a high inclination, but whereas the eccentricity would subsequently be damped by tidal dissipation, the high inclination would remain and would testify to the resonance passage.

Discussion

Because of the neglect of secular variations in all published analyses of the orbits and masses of the uranian satellites, including that of Veillet[4], the results obtained from these investigations must be treated with caution. The masses in particular, derived from an inappropriate expression for pericentre precession, may well be considerably in error. Unfortunately, it does not appear possible to correct these omissions and re-derive better values for the satellite masses without a reconsideration of all the available data. Such an investigation is beyond the scope of this paper. A thorough re-analysis of the uranian satellites' orbital elements, taking into account the present results, would probably start with the establishment of osculating elements from short ($\leq$5 yr) spans of data, and then attempt to model the longer-term variations in these osculating elements in terms of the theory of secular perturbations. Hints of such variations are already present in the large differences between some of the orbital elements derived by Harris in 1950, Dunham in 1970 and Veillet in 1983. Apart from yielding an improved set of masses, such an investigation may be expected to shed light on several other outstanding problems. These include: (1) a discrepancy of ~0.2° between the pole direction of Uranus deduced from stellar occultation studies of the rings[18,22] and that obtained by Veillet[4]; (2) a discrepancy between the observed period of the Miranda-Ariel-Umbriel longitude variation and that deduced from Veillet's masses[23]; and (3) the question of whether any 'secular librations' exist among the satellites, as suggested by Greenberg[17]. The results shown in Figs 2 and 3 and Table 3 indicate that Titania and Oberon could well be involved in such a libration, involving the arguments $\tilde{\omega}_4$-$\tilde{\omega}_5$ and/or Ω_4-Ω_5.

Although it does not seem possible, at present, to ascribe the apparently undamped eccentricities of Miranda and Ariel to secular perturbations alone, it is clear that a more realistic estimate of tidal damping timescales for the uranian satellites must take such perturbations into account. An investigation of this matter will form the subject of a future paper.

Finally, we note that the encounter with Uranus of the Voyager 2 spacecraft on 24 January 1986 should provide several pieces of information relevant to uranian satellite dynamics. Most important would be direct measurements of the satellite masses, which now must be considered as unknown. Only Miranda is to be approached relatively closely by the spacecraft, but all necessary steps should be taken to maximize the chances of successful mass determinations for the other four satellites, especially Ariel. Of secondary importance, but also valuable, would be the determination of a complete set of osculating orbital elements for the satellites, based on far-encounter and near-encounter imaging. In particular, an accurate Voyager determination of Miranda's node, combined with extensive ground-based observations of this satellite carried out over the past 9 yr (refs 21, 24, 25) should lead to an independent estimate of Ariel's density through equation (15).

We thank D. J. Stevenson, R. Hamilton Brown and W. Reid Thompson for useful discussions. This research was supported by NASA grants.

Requirement of stereospecific alignments for initiation from the simian virus 40 early promoter

The distance between the simian virus 40 early promoter elements has been altered by inserting either odd or even multiples of half a DNA turn. There are marked differences in the in vivo *effects of these two types of insertions on initiation of transcription from this promoter.*

DISSECTION *in vivo* and *in vitro* of the simian virus 40 (SV40) early promoter region (see Fig. 1) has shown that it contains two overlapping promoters for RNA polymerase B (II), the early-early (EE) and late-early (LE) promoters (see refs 1-5 and refs therein). Accurate initiation of RNA synthesis at the early-early start sites (EES) requires the TATA box element, whereas the 21-base pair (bp) repeat region and the enhancer are both essential for efficient transcription. Efficient initiation of transcription from the late-early start sites (LES) also requires the presence of the 21-bp repeat region and of the enhancer, and occurs in the apparent absence of a TATA box. Six G·C motifs (Fig. 1; I-VI) are involved in the function of the 21-bp repeat region, but they do not contribute equally to stimulation of transcription from the EES and LES, G·C motifs I-III being the most important for initiation from EES, whereas initiation from LES is more dependent on G·C motifs IV-VI[4,5]. A systematic mutational dissection of the enhancer region has revealed that several sequence motifs are indispensable to its function, and that the same sequences are reponsible for enhancement of transcription from both the EES and the LES[6].

In vitro transcription studies have shown that different *trans*-acting factors bind specifically to these *cis*-acting regulatory sequences. The TATA box factor binds to the TATA box to form a stable complex; this is a prerequisite for specific initiation of transcription[7,8]. The transcription factor Sp1 binds specifically to the 21-bp repeat region and stimulates transcription from the EES and LES[4,9-11]. Different *trans*-acting factor(s) bind(s) to the enhancer and stimulate(s) transcription from both the SV40 early and heterologous promoter elements[12-15]. Moreover, footprinting experiments have shown that binding *in vitro* of the Sp1 factor[4,10,11] and enhancer[16] factor(s) to the 21-bp repeat and the enhancer regions, respectively, is severely impaired by mutations known to be detrimental to the *in vivo* function of these promoter elements.

Therefore, at least three different proteins (or sets of proteins), interacting with three different promoter elements, are required to allow RNA polymerase B to initiate transcription from the SV40 early promoter. However, both the 21-bp repeat element and the enhancer can operate when in an inverted orientation (refs 4-6 and refs therein), although they do not exhibit any obvious symmetry in their DNA sequence. In addition, the enhancer can stimulate transcription to some extent when inserted some distance away[17-19]. Thus, rather than stimulating transcription by interacting with each other and/or with RNA polymerase, the factors that bind to the 21-bp repeat and enhancer regions could induce a local perturbation in the structure of the DNA helix, which could be propagated close to the start sites, where it would facilitate initiation of transcription by RNA polymerase B. We have altered the distance between the three SV40 early promoter elements by inserting either odd or even multiples of half a turn of the DNA helix (DNA turn), and demonstrate here that there are marked differences in the *in vivo* effects of these two types of insertions on initiation from this promoter, which strongly suggests that protein-protein interactions are involved in activation of transcription initiation from an RNA polymerase B promoter.

Construction and assay of spacing mutants

All spacing mutant recombinants are similar to pDHB3.SV1 (ref. 5) and pSEGO (ref. 4) in that they contain the SV40 early promoter region (from *Hpa*II to *Hin*dIII; Fig. 1) inserted upstream from a promoter-less rabbit β-globin gene (position −9 to +1,650) and a complete rabbit β-globin gene (including its promoter region), acting as an internal 'reference' gene. The pS series contains 4-29-bp inserts at the *Sal*I site (position 32) between the 21-bp repeat and the TATA box region of pSO. The pSE series harbours 5-25-bp inserts at the *Bam*HI site (position 101) between the enhancer and 21-bp repeat region of pSEGO (similar to pSO, but containing a single 72-bp sequence). In the pSR series, inserts of 4-21 bp are introduced between the TATA box and the inverted 21-bp repeat region (from position 40 to 103) of pSRO (otherwise identical to pSO). The pSR series also contains 4-7-bp deletion mutants (Fig. 1). For most spacer lengths, we constructed two recombinants, A and B, with different inserted sequences (usually the same sequence in both orientations).

After transfection of the recombinants into HeLa cells, RNA initiated from the SV40 early promoter was measured by quantitative S_1 nuclease mapping using two probes as described previously[4,5]. The amount of RNA initiated from the reference β-globin gene (GLOB band in Figs 2-4) and the total amount of RNA initiated from the SV40 early promoter region (EP band in Figs 2-4) was determined with probe A. Probe B was used to accurately map and quantitate RNA initiated from the EES and LES of the SV40 early promoter (Figs 1-4; under the present stringent S_1 nuclease conditions, the bands corresponding to LES2 and LES3 were not resolved and no attempt was made to measure initiation from LES1—see refs 1 and 5 for a discussion of these points).

DNA turn-dependent insertions

Between the enhancer and 21-bp repeat region. Introduction of 10 bp and 21 bp, both near-integral multiples of the 10.5 bp per turn of B-DNA *in vitro*[20], between the 21-bp repeat region and the enhancer of pSEGO, causes an ~50% decrease in RNA

initiated from all EES and LES (pSE10 and 21 mutants; Figs 1, 2, 5). In marked contrast, alterations of the distance between these two promoter elements by odd multiples of half a DNA turn result in dramatic 80–90% decreases in transcription initiated from all start sites (pSE5, 15 and 25 mutants; Figs 1, 2, 5). This is well illustrated by the 'cyclic' variations in the total amount of RNA initiated from the SV40 early promoter region estimated from the intensity of the band EP in Fig. 2. As the EE and LE promoters share a common element—the 21-bp repeat region—these results indicate that efficient transcription from both the EES and LES requires stereospecific alignments between some elements of the enhancer and of the 21-bp repeat region (see below for further discussion). The present results also confirm our previous conclusion[1] that the enhancer is required for activating transcription from both the SV40 EE and LE promoters.

Several lines of evidence support the conclusion that the observed variations reflect modifications of the effect of the enhancer and not of the activity of a putative upstream element similar to the 21-bp repeat region, which would also be contained in the enhancer sequence. First, no mutations within the enhancer have been found that affect its activity specifically when it is in close apposition to the 21-bp repeat region, but not when it is moved far away[6]. Second, the level of all RNA species initiated downstream from the enhancer varies in parallel, which is in marked contrast to the differential variations observed with insertions between the 21-bp repeat region and the TATA box (see below). Third, there is no rapid overall decrease of RNA synthesis as the length of the 'even inserts' is increased and no decrease at all with 'odd inserts', which again is in marked contrast to the variations observed in either the pS or pSR series (see below). The last observation probably reflects the increasing possibility of achieving a proper alignment as the length of the odd inserts increases.

The sequence element(s) which, within the enhancer domains, is (are) responsible for this DNA turn-dependence of activation of transcription is (are) unknown. The SV40 enhancer is composed of at least two domains, A and B, which are very inefficient by themselves but, when juxtaposed, stimulate transcription from the early promoter by three orders of magnitude[6]. In an enhancer containing a single 72-bp sequence, domain A, which is centred on the *Sph*I site, spans the 3′ moiety of the 72-bp sequence, whereas domain B roughly spans the 5′ moiety of the 72-bp sequence and sequences located further upstream up to approximately the *Pvu*II site (ref. 6; see also Fig. 1). Inserting fragments of various lengths (4–50 bp) between domains A and B does not markedly affect the enhancer activity[6], indicating that there is apparently no stringent position requirement between the two domains nor between domain B and the 21-bp repeat region. (However, longer insertions result in a strong decrease of enhancer activity; see ref. 6.) It appears, therefore, that the cyclic variations in RNA synthesis observed in the pSE

Fig. 1 (Opposite) General organization and sequences of the SV40 early promoter region and the pS, pSE and pSR mutant series. *a*, Organization of SV40 early promoter region in recombinant pSO. Some key natural or engineered (*Bam*HI, *Sal*I) restriction sites are indicated with their position (BBB system; see ref 29) in parentheses. ▼, Location of the TATA box; the sequence of pSO (noncoding early strand) between coordinates 5,227 and 117 is shown. The SV40 wild-type bases mutated during the creation of the *Bam*HI (101) and *Sal*I (32) sites (dashed boxes; see ref. 4), are indicated in parentheses below the main sequence. The TATA sequence is boxed. The position of the early-early start sites (EES1 and EES2, arrows) and late-early start sites (LES1, LES2 and LES3, dashed arrows) are indicated (see ref. 1 and text). The position of start site (A) corresponding to the G residue at position 11 is indicated (see Fig. 3 and text). The directly repeated 21-bp sequences (I and II), and the 22-bp sequences are delimited by vertical, downward-pointing arrows. The six G·C motifs 5′ CCGCCC 3′ are underlined and identified by roman numerals[4]. The sequences inserted (underlined) in the pSE and pS mutant series are represented on the left- and right-hand sides below the pSO sequence, respectively. The pSE mutant series is derived from pSEGO (ref. 4), which contains a single 72-bp sequence, whereas the pS mutant series is derived from pSO which contains a complete 72-bp repeat (see below). Sequences of pSN (*b*) and pSRO (*c*), in which the 21-bp repeat region is in the natural and reverse orientation, are shown. Boxed sequences at the borders of the 21-bp repeat region correspond to the 4-bp inserts generated during the construction of these recombinants. pSN and pSRO have a complete 72-bp repeat. The sequences deleted or inserted (underlined) in the pSR mutant series are indicated below the pSRO sequence. The relative amount of RNA initiated at EES1, EES2 and LES2+3 after transfection of the various recombinants into HeLa cells was estimated by scanning autoradiograms (similar to those shown in Figs 2-4) from at least three different quantitative S_1 nuclease mapping experiments using different plasmid preparations. After correction for transcription from the reference β-globin gene[4,5] the results were expressed relative to pSO (for the pS and pSR series) or pSEGO (for the pSE series), taken as 100%.

Methods. Construction of pSO, pSRO and pSN. pSO, which is identical to pSEGO[4] but contains a complete 72-bp repeat, was constructed by ligating the *Hin*dIII/*Bam*HI fragment (position 5,171–101, BBB numbering system[29]) of pSEGO into the equivalent position of pSVTK2 (ref. 4). pSRO and pSN were constructed as follows: pTK4 is similar to pHB4 (ref. 4), but contains a complete 72-bp repeat, a *Sal*I site at position 32 (by exchange of the *Hin*dIII (5,171)/*Nco*I(37) fragment with that of pSEGO), and lacks the *Sal*I and *Sph*I sites in the pBR322 sequence (destroyed by repairing with Klenow DNA polymerase and blunt-end ligation). pTK4 was digested with *Nco*I (position 37) and *Bam*HI (position 101), and treated with Klenow DNA polymerase in the presence of all four dNTPs. The fragments were ligated back to yield two recombinants (pTK421N and pTK421R) containing the 21-bp region in either orientation between the repaired *Nco*I and *Bam*HI sites. The *Sal*I/*Kpn*I fragments (positions 32 and 294) of these two recombinants were isolated and ligated to pSO digested by *Sal*I and *Kpn*I to yield pSN and pSRO. Construction of mutants with insertions and deletions between the 21-bp repeat region and the TATA box region: Three sets of two overlapping complementary oligonucleotides (10-, 15-, 21-mers) with *Sal*I protruding 5′ ends were synthesized by the phosphotriester method as described previously[30]. The oligonucleotides were phosphorylated, mixed, heated to 60 °C for 30 min and then hybridized at room temperature for 1 h. pSO and pSR DNAs were digested with *Sal*I and ligated to the oligonucleotides to yield the pS (pS10, 15, 21) and pSR (pSR10, 15 and 21) mutant series, respectively, with inserts in either orientation (A and B). pS4 and pSR4 were constructed by blunt-end ligation of pSO and pSR cleaved with *Sal*I and repaired with Klenow DNA polymerase. pSB24 containing a different 4-bp insert was constructed by replacing the *Hin*dIII/*Nco*I (5,171–37) fragment of pSO with that of pDB3.B24[5]. pS28A, pS28B and pS29 were obtained during the cloning of pS10 (see Fig. 1). Deletion mutants of pSR were prepared as follows: 30 µg of pSRO was digested with *Sal*I, phenol–chloroform-extracted, precipitated with ethanol, and suspended in 400 µl S_1 nuclease mixture (30 mM NaoAc *p*H 4.5, 3 mM $ZnSO_4$, 400 mM NaCl). 250 units of S_1 nuclease were added, and after 10 min at 25 °C the reaction was stopped by adding 70 µl of 2 M Tris-HCl *p*H 8.0, 0.2 M EDTA. After phenol-chloroform extraction, the DNA was precipitated with ethanol and suspended in 30 µl 10 mM Tris-HCl *p*H 8.0, 1 mM EDTA. DNA (1 µg) was treated with Klenow DNA polymerase in the presence of all four dNTPs, then ligated to yield pSRΔ7–pSRΔ4 deletion mutants . Construction of mutants with insertions between the 21-bp repeat and the enhancer: The pSE mutant series was constructed by shot-gun ligation of synthetic oligonucleotides[31]. Briefly, eight sets of different overlapping oligonucleotides corresponding to the sequence between the *Bam*HI and *Nsi*I sites (positions 101 and 126) plus additional sequences of 5, 10, 15 and 21 bp at the *Bam*HI extremity were chemically synthesized. The oligonucleotides were phosphorylated at their 5′ ends, mixed and hybridized as above, and ligated directly into pSEGO (ref. 4) digested with *Nsi*I and *Bam*HI to yield the pSE mutant series. pSE25 (A and B) were constructed by cleaving pSE21 with *Bam*HI, followed by blunt-end ligation after reparation with Klenow DNA polymerase. Recombinant DNAs were grown and prepared as described previously[4] and monitored for possible rearrangements by restriction enzyme analysis. Sequence and orientation of the DNA inserts were determined by dideoxynucleotide sequencing of both strands using double-stranded plasmid DNAs as template, and synthetic oligonucleotide primers[32].

series reflect the necessity of a stereo-alignment between some elements contained in enhancer domain A and the G·C motifs of the 21-bp repeat region.

Between the 21-bp repeat and TATA box regions. In agreement with our previous results[4,5], insertion of DNA segments of increasing length between the 21-bp repeat and the TATA box regions leads to a rapid and drastic decrease in RNA initiated at the major early-early start sites, EES1 (Figs 1, 3, 5). It is, however, remarkable that 10- (pS10A and B) and 21-bp (pS21A and B) inserts are consistently less detrimental to transcription than 4- (pS4 and pSB24) and 15-bp (pS15A and B) inserts, respectively. It is particularly striking that the intensity of the two bands labelled EES2 in Fig. 3 varies in exactly the opposite way (see also Figs 1, 5). These two bands correspond to minor start sites which, contrary to EES1, do not disappear when the TATA box is mutated[1], but are absent when the row of Ts located immediately upstream from the TATA box is mutated (M. Pauly, M. Wintzerith, H.M. and P.C., unpublished results). It is probable, therefore, that this row of Ts acts as a substitute TATA box to direct initiation of transcription at EES2.

We conclude that some upstream elements must be located stereospecifically with respect to a given TATA box for initiation of transcription under its control to occur. To characterize these elements further, we constructed plasmid pSN (Figs 1, 4), which contains a 4-bp insertion at both ends of the 21-bp repeat region, so as to maintain the TATA box and enhancer elements close to their natural steric relationship. The pattern of initiation in pSN (EES2 favoured compared with EES1; Figs 1, 4) is very similar to those of pS4 and pSB24, which possess a single 4-bp insertion between the TATA box and the 21-bp repeat region. This result indicates that it is the steric location, relative to the TATA box, of the 21-bp repeat region rather than that of the enhancer which is responsible for the occurrence of initiation preferentially at EES1 or EES2. However, as expected from the results obtained with the pSE5 mutants, there was a general decrease in transcription from pSN compared with pS4 and pSB24.

Several lines of evidence support the conclusion that the region at which transcription initiation occurs is primarily determined by the location of the 21-bp repeat region, and that the TATA box element selects the precise site of initiation. Moving the 21-bp repeat region away from the TATA box region by >20 bp results in a dramatic decrease of transcription from both EES1 and EES2 start sites, whereas initiation from the LES is concomitantly increased, indicating that the location of the 21-bp repeat region is not optimal for initiation from LES. Using longer DNA inserts, we found that initiation at LES disappears, whereas new start sites located within a 30-50-bp region downstream from the 21-bp repeat region appear[4]. Note that with insertions of ≤21 bp there is very little initiation of transcription within the inserted sequence, as the band corresponding to the endpoint of homology between the wild-type probe and RNA transcribed from the spacing mutants is very weak, with the exception of mutants pS28A and B (not shown) and pS29 (Fig. 3, right-hand arrow). Whether the same late-early start sites were used in all insertion mutants cannot be determined from the present experiments, as all start sites in the A+T-rich region (positions 14–31) yield the same LES2+3 bands under the S_1 nuclease conditions used in this study (see above; there is, however, an additional start site A (Fig. 3) which appears to be preferentially used in some mutants). Thus, it is not possible from the present study to determine whether initiation of transcription from the various LES is also DNA turn-dependent.

Insertions and deletions between the inverted 21-bp repeat and TATA box regions. The 21-bp repeat region can stimulate initiation of transcription from the EES and LES, even when inserted in the reverse orientation in the SV40 early promoter region[2,4,5,21]. The pSR mutant series (Fig. 1) was constructed to determine whether altering the distance between the inverted 21-bp repeat region and the TATA box region would result in

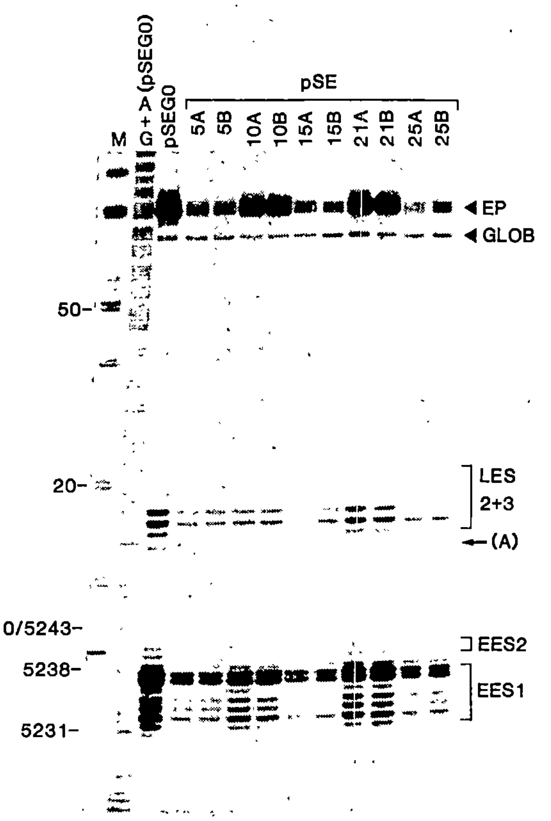

Fig. 2 Effect of insertions between the 21-bp repeat region and the enhancer on transcription initiated *in vivo* from the SV40 early-early and late-early start sites. HeLa cells were transfected with the pSE mutant series (as indicated at the top of each lane) and cytoplasmic RNA was analysed by quantitative S_1 nuclease mapping as described previously[4,5], using probes A and B which correspond to the [^{32}P]5'-end-labelled coding strand of the *Bst*NI fragment of the rabbit β-globin gene (position +138 to −84) and the [^{32}P]5'-end-labelled SV40 early coding strand of the *Hin*dIII to *Cla*I fragment of pSEGO, respectively. EP indicates the S_1 nuclease-resistant DNA fragment that arises from the homology between probe A and the SV40-globin hybrid transcripts. GLOB corresponds to the S_1 nuclease-resistant DNA fragment of probe A expected for RNA initiated at the start site of the reference β-globin gene contained in these recombinants. The S_1 nuclease-resistant bands EES1, EES2 and LES2+3 correspond to RNA initiated from the early-early and the late-early promoters, respectively, as described previously[1,5] and in the text. The arrow labelled A points to a resistant band corresponding to start site A indicated in Fig. 1. Numbers on the left-hand side pointing to the A+G sequence ladder of probe B indicate the SV40 nucleotide positions using the BBB numbering system. Lane M, size markers ([^{32}P]5'-end-labelled *Msp*I digest of pBR322).

the same critical DNA turn-dependence as that observed with the 21-bp repeat region in its natural orientation. In mutant pSRO, initiation is low from EES1 and high from EES2 compared with the wild-type early promoter in pSO, and similar to that of mutants pS4 and pSB24 containing a 4-bp insertion between the 21-bp repeat region and the TATA box (Figs 3-5). This observation is particularly striking because the first G·C motif (VI) in pSRO is at the same distance from the TATA box as the first G·C motif (I) in pS4 or pSB24, that is, approximately half a turn off from the natural configuration. Introducing deletions (pSRΔ4, pSRΔ5, pSRΔ6 and pSRΔ7) or an insertion of approximately one-half a DNA turn (pSR4) in pSRO, thereby rebuilding a wild-type architecture, resulted in a pattern of initiation from EES1 and EES2 that is very similar (EES1 much higher than EES2) to that observed with the naturally spaced promoter of pSO (Figs 1, 4, 5). Initiation from EES1 is the highest in the deletion mutant pSRΔ6, whereas it is concomitantly the lowest from EES2 (Figs 1, 4). A drastic decrease in RNA initiated at both EES1 and EES2 is observed with inserts of increasing length, but the pattern of initiation from these start sites shows the same dependence on DNA turn as in the pS series (compare pSRO, pSR10A and B and pSR21A and B with pSR4, pSR15A and B. We conclude that, even when inverted, the 21-bp repeat region has to be correctly aligned with the TATA box element to preferentially activate initiation of transcription from the EES1, and similarly will preferentially stimulate initiation from the EES2 when aligned with the T-rich substitute TATA box.

As in the case of the pS spacing mutant series, in which the 21-bp repeat region is in the normal orientation, initiation from the late-early start sites, LES2+3, of the pSR series increased with the length of the inserts. Finally, it should be stressed that all pSR recombinants contain a 4-bp insertion between the 21-bp repeat region and the enhancer. As introducing one-half a DNA turn between the enhancer and the 21-bp repeat region in its natural orientation results in a striking decrease of intiation from all start sites (pSE5 in Figs 2, 5), it is likely that these additional 4 bp are required to stereo-align some elements of the enhancer and the inverted 21-bp repeat region. In fact, the additional insertion of 5 bp between the 21-bp repeat region and the enhancer of pSRΔ4 results in a strong decrease in initiation from all start sites (data not shown).

A role for protein-protein interactions

Our results are most easily interpreted along the lines that protein-protein interactions are involved in activation of transcription initiation. An alternative possibility, that factors bound to the 21-bp repeat region and the enhancer induce stereospecifically related local perturbations in the DNA helix that are recognized by the rest of the transcription machinery, appears less likely in the light of our present knowledge.

The results obtained by inserting odd and even multiples of half a DNA turn between the 21-bp repeat region and the normal or substitute TATA box regions demonstrate clearly that efficient activation of initiation of transcription requires a stereospecific alignment between these elements, and that the region at which initiation of transcription occurs is determined primarily by the position of the 21-bp repeat region. Studies *in vivo* (refs 3-5, 21 and refs therein) and *in vitro* (refs 2, 4, 22 and refs therein) have shown that the first three G·C motifs (most notably GC-I) of the 21-bp repeat region (Fig. 1) are essential elements of the SV40 early promoter. *In vitro*, the transcription factor Spl contacts several G residues (underlined) of the 3' $G\underline{G}C\underline{GGG}$ 5' motif (refs 10, 11 and our unpublished results). A different factor binds to the TATA box (refs 7-9, 23; and our unpublished results). Thus, initiation of transcription appears to require a stereospecific alignment between the Spl and TATA box factors, which led us to propose the following model.

The transcription machinery (presumably RNA polymerase B) interacts primarily with at least the first of the three Spl factor molecules (bound to G·C motifs I-III) which are all located on one side of the DNA helix. The TATA box factor, when correctly positioned by a properly aligned TATA box, interacts with the polymerase and directs it to initiate principally at the corresponding start site(s) (EES1 in the wild type; mutating the TATA box results in the disappearance of RNA initiated at the EES1 both *in vivo* and *in vitro*[1]). Misalignment caused by inserting half a DNA turn leads to the preferential use of the T-rich substitute TATA box which is located on the other side of the helix and controls initiation at the EES2. Spl factors bound to G·C motifs II and III may either interact directly with the trancription machinery or interact with each other and their effect be mediated by the Spl factor bound to G·C-I. Whether this Spl factor and the TATA box factor interact directly with each other as well as with RNA polymerase, for instance to stabilize their respective interactions with their cognate binding sites, cannot be predicted from our present study. However, stable binding of Spl factor to the 21-bp repeat region *in vitro*

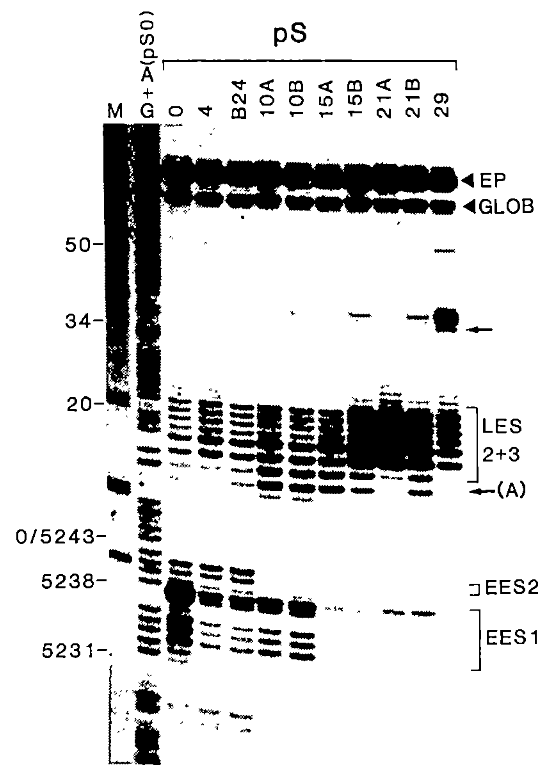

Fig. 3 Effect of insertions between the 21-bp repeat and the TATA box regions on trancription initiated *in vivo* from the SV40 early-early and late-early start sites. HeLa cells were transfected with the pS mutant series (as indicated) and cytoplasmic RNA was analysed by quantitative S_1 mapping using a probe B prepared from pSO. Symbols are as described in Fig. 2 legend. The arrow on the right-hand side indicates the beginning of all insertions (SV40 coordinate 34). Start site A corresponds to position 11.

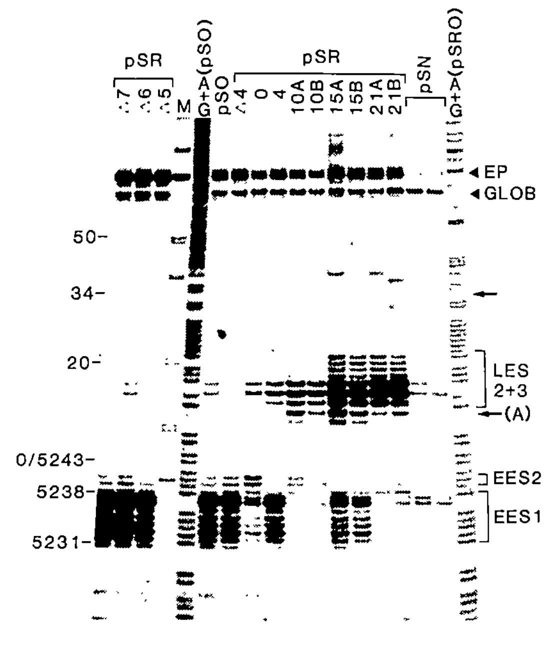

Fig. 4 Effect of deletion and insertion between the inverted 21-bp repeat region and the TATA box region on transcription *in vivo* from SV40 early-early and late-early start sites. Cytoplasmic RNA extracted from HeLa cells transfected with the pSR series mutants (as indicated) was analysed by quantitative S_1 nuclease mapping using a probe B prepared from pSO. Symbols are as described in the legends to Figs 2, 3. The arrow on the right-hand side of the figure indicates the beginning of all insertions (position 34). Start site A corresponds to position 11.

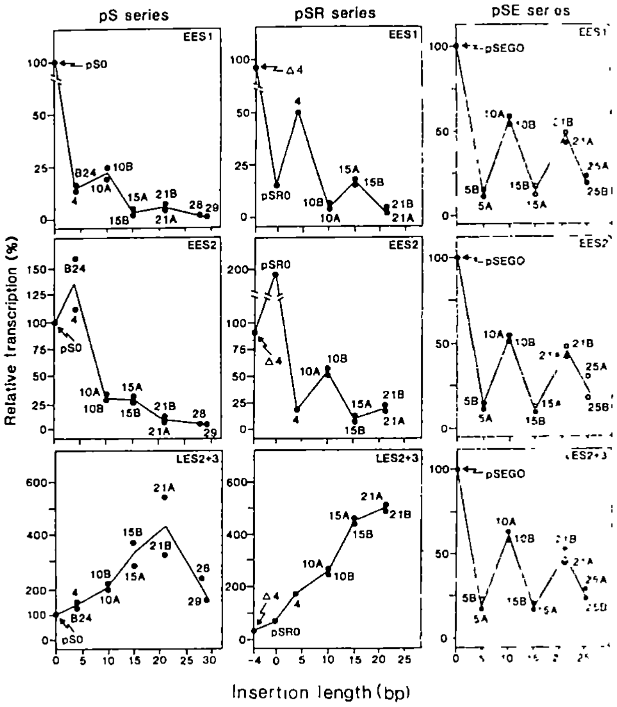

Fig. 5 Diagramatic comparison of the results obtained with the various insertion mutants. The length of the insertions (or deletion, pSR series) between the 21-bp repeat region and the TATA box region or the enhancer is indicated on the abscissa and the relative efficiency of transcription is given on the ordinate. The left-hand panels represent the results of the pS mutant series for transcription starting at EES1, EES2 and LES2+3, whereas the right-hand and centre panels show the results for the pSE (insertions between the TATA box and the 21-bp repeat region) and pSR (insertions between the TATA box and inverted 21-bp repeat region) mutant series, respectively. The values which are taken from Fig. 1 are expressed relative to EES1, EES2 and LES2+3 of pSO (for the pS and pSR series) and pSEGO (for the pSE series).

does not require the presence of the TATA box region[23]. Increasing the distance between the 21-bp repeat region and the TATA box (or its substitute) either prevents the transcription machinery from interacting efficiently with the bound TATA box factor (even when properly aligned) or prevents the TATA box factor from binding efficiently to the TATA box, and results in the observed rapid decrease in initiation from the EES1 and EES2. Weak substitute TATA box elements will then direct the transcription machinery to preferentially initiate at the various LES. With longer inserts, similar weak multiple substitute TATA box elements (see ref. 24) will direct the transcription machinery to initiate at multiple sites in the 30–50-bp region located immediately downstream from the 21-bp repeat region. Alternatively, RNA polymerase bound to the 21-bp repeat region may initiate at multiple sites without the help of the TATA box factor. Such a model readily accounts for the observation that there is no marked overall decrease in RNA initiated from the SV40 early promoter region in the insertion mutants (see band EP in Fig. 3, whose intensity reflects the total amount of RNA initiated from the SV40 early promoter region).

The study of the pSR series shows clearly that the 21-bp repeat region, even when inverted, has to be stereo-aligned with the TATA box or the substitute T-rich TATA box to preferentially stimulate initiation at the EES1 or EES2, respectively. It is particularly striking that the pattern of initiation of the wild-type naturally spaced pSO recombinant (EES1 much higher than EES2) is best reproduced with the inverted 21-bp repeat region recombinants pSR4 and pSRΔ6, whose position of the corresponding G·C-rich motifs is separated by 10 bp when their

TATA boxes are aligned. Thus, our results suggest strongly that equivalent protein–protein contacts can be established between the transcription machinery and the factor(s) bound to the G·C motifs, irrespective of the orientation of the 21-bp repeat region. This is very surprising because there is no apparent symmetry in the sequence of these motifs. Several explanations can be proposed to account for this paradox: (1) symmetry may be present in the G·C motif, even though it is not readily apparent; (2) Sp1 factor could be an asymmetrical molecule with equivalent protein interaction sites at either end; (3) the protein with which Sp1 factor interacts (for instance, RNA polymerase which has multiple subunits) may possess symmetrical protein interaction sites; (4) Sp1 factor may be composed of two functional domains linked by a flexible stem: one DNA-binding domain which would specifically recognize the G·C motifs, and one protein-interacting domain which would interact with some component of the transcription machinery. We find the two-domain hypothesis attractive because such separate domains for DNA binding and activation of transcription by protein interaction with RNA polymerase are known to exist in repressor proteins of *Escherichia coli* λ phages[25-27]. In this respect, we note that in the two inverted 21-bp region recombinants pSR4 and pSRΔ6 (see above) and in the wild-type recombinant pSO (which exhibit the same patterns of initiation at the EES1 and EES2), the N-7 of the G residues in the G·C motifs, which are protected by Sp1 factor from methylation by dimethylsulphate[11], are located on the same side of the DNA helix when their TATA box sequences are aligned (data not shown).

Our present results and those reported elsewhere[6] demonstrate that efficient initiation of transcription from the entire SV40 early promoter region requires a stereospecific alignment between some element(s) contained in domain A of the enhancer and the 21-bp repeat region. Transcriptional factors are known to bind *in vitro* to domain A[13,14,16]. Thus, it is likely that they have to be stereo-aligned with Sp1 factors for the enhancer to efficiently stimulate transcription. Note that the Sph motifs present in domain A, known to be important for enhancer activity[6], are separated by approximately one helical turn from one another and by a multiple of 10 bp from the G·C motifs. Thus, protein(s) bound to these Sph motifs and to the G·C motifs may be on the same side of the helix, and may specifically interact with each other and/or independently with some element(s) of the transcription machinery (for example, RNA polymerase; see above). Note that Sp1 factor can bind to the 21-bp repeat region *in vitro* in the absence of the enhancer sequence[10,23], whereas proteins appear to be less stably bound to the enhancer in the absence of the 21-bp repeat region[16], and that transcription can occur *in vitro* (but not *in vivo*) from an enhancer-less early promoter, although at a reduced rate[2,14].

It appears, therefore, that the assembly of proteins bound to the various elements of the SV40 early promoter could constitute a broad protein interaction region located mainly on one side of the DNA helix, where it could act as a specific recognition region for RNA polymerase B, which itself is composed of multiple subunits[28]. The part played by the transcriptional factors bound to the 21-bp repeat and the TATA box region would be to anchor stably RNA polymerase to enable it to initiate at the start sites, and perhaps also to have a role in its activation. The protein(s) bound to enhancer domain A would participate in activation of transcription initiation, either directly by interacting with RNA polymerase, or indirectly through contacts with the protein(s) bound to the 21-bp repeat region. All these interactions contribute to increase the transcription machinery concentration at a given promoter region which has to compete successfully with the rest of the very large genomic DNA for efficient initiation of transcription to occur. A DNA looping mechanism may account for the persistence of some enhancer activity (see refs 1, 19) as it is moved away from the other promoter elements. That the enhancer, and not only the 21-bp repeat region, can activate transcription irrespective of its orientation, can be explained by the hypothesis that proteins bound to it are composed of two distinct functional domains linked by a flexible stem (see above). The fact that enhancer domain B (essential for enhancer activity) apparently does not need to be stereospecifically aligned makes it unlikely that proteins bound to that domain belong to the broad RNA polymerase B binding and activation complex discussed above. However, *in vitro* studies[13,14] indicate that proteins bound to domain B are involved in the stimulation of transcription observed *in vitro* with templates that contain enhancers, suggesting that, nevertheless, these proteins interact in some way with the transcription machinery.

In conclusion, our results clearly support the view that multiple protein–protein interactions have a key role in the generation of an active transcriptional initiation complex at a promoter, which is a very large specific nucleoprotein structure composed of multiple sequence elements recognized by different cooperating factors. It is likely that this concept can be generalized to other class B(II) promoters, as the same DNA turn dependence has been observed when the SV40 enhancer activates transcription from the adenovirus-2 major late promoter (our unpublished results). *In vitro* studies aimed at reconstructing transcription initiation complexes from purified factors and RNA polymerase are in progress to investigate the validity of our model.

A very high energy γ-ray burst from the Crab pulsar

P. N. Bhat, P. V. Ramanamurthy, B. V. Sreekantan & P. R. Vishwanath

Tata Institute of Fundamental Research, Homi Bhabha Marg,
Bombay 400005, India

The Crab pulsar, a source of pulsed photons over a wide range of energies, has been observed in the TeV energy range by several groups using the Atmospheric Cerenkov technique[1]. Time-averaged phasograms have shown signals on only a few occasions. The Durham University group[2] detected pulsed TeV γ-rays during two transients lasting 15 min, each in October, 1981, while the Ooty group[3,4] has shown that the transient duration could be on time scales of minutes or even seconds. In our recent observations, we identified a 15-min interval on 23 January 1985 during which pulsed TeV γ-rays were detected at a 5.1 sigma level at the same phase as the radio main pulse. Our inference of transient pulsed emission is strengthened by the absence of a signal in a nearby control telescope tilted 8° away from the pulsar and evidence for signal in another telescope 11 km away. We present here an analysis of the data from our 1984–1985 observations.

The Ooty array (for details, see refs 3 and 5), normally operated with 18 mirrors, was split up and operated at two sites, site A and site B, 11 km apart. At site A, eight large mirrors, with a diameter of 1.5 m, were used and at site B, 10 small mirrors, with a diameter 0.9 m were used. For some of the runs at site A, the eight large mirror array was further split into two halves with one half of the array (A1) pointing at Crab and the other half (A2) at a point 8° south of Crab. The trigger was derived from a three-out-of-four majority logic at site A and a coincidence of four mirror banks (at least two mirrors in each bank) at site B. The chance coincidence rates of the arrays were also monitored. The arrival time of the event was recorded to an accuracy of 0.1 ms at both the sites. In addition, the pulse from the photomultiplier on each mirror at site A was digitized with a LeCroy ADC (analog digital converter). The time keeping accuracy was 0.03 ms which was achieved with a NNSS (Navy Navigation Satellite System) satellite timing receiver. The average trigger rate at site A was 500 per min when the array was not split and about 300 per min for each of the half arrays (A1 and A2) when it was split. The average rate at site B was about 120 per min. Such high rates resulted from several factors: large mirror areas, majority logic and 4° apertures employed in the experiment. These rates convert to a threshold of 800 GeV for the full array at site A and 1.2 TeV for arrays A1 and A2. The energy threshold at site B was 2.2 TeV.

Data were taken during December 1984 and January and February 1985. The February runs were rejected because of persistent lightning. Data on Crab pulsar were taken on nine nights at site A, out of which the two array (A1 and A2) mode was used on four nights. At site B, there were 11 nights of observation, out of which there was overlap with observations at site A during six nights only. Total observation times at sites A and B were 1,436 and 1,908 min respectively. The total time of simultaneous observations at the two sites was 1,004 min, out of which the array at site A was operated in the two half array mode for 540 min.

The analysis of the data was carried out using the pulsar elements applicable to the epoch of our observations obtained from contemporaneous radio observations (by A. G. Lyne). A barycentric time reduction programme and related ephemeris (due to D. Richards and I. Shapiro respectively) were used to compute the number of Crab pulsar cycles at the barycentre for every half hour at the observation site. The pulsar phase for each event was then computed by interpolation (checked to be accurate to better than 0.0016%) and folded to obtain the phasogram for the pulsar. The number of bins used for the phasogram is 20.

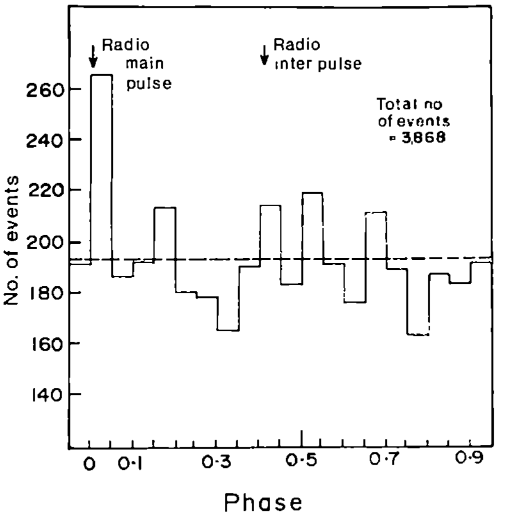

Fig. 1 The phasogram of events from array A1 looking at the Crab pulsar during the 15-min duration 1711 to 1726 h on 23 January 1985. Each bin has a width of 1.65 ms. The average for the whole phasogram is shown by the horizontal dashed line.

The data were split into mini-runs of duration five minutes each and a phasogram was constructed for each mini-run. Phasograms from three consecutive mini-runs were added to get one 15-min phasogram. There were such 116 independent 15-min phasograms from data at site B and 90 from site A, giving a total of 206 phasograms. When these phasograms were inspected for significant peaks, we found one 15-min interval during the night of 23 January 1985 from the half array A1 (looking at the Crab pulsar) at site A showing a 5.1 sigma peak at the position of the radio main pulse. In the phasogram, which is shown in Fig. 1, there are 72 excess events during the 15-min interval in the first phase bin when the average was 193 events. There is a minor (1.5σ) peak at the position of the radio inter-pulse. Figure 2*a*, *b* shows the observed number of events in the first phase bin and the average per-bin from the entire phasogram for all the three mini-runs from arrays A1 and A2 looking at and away from the pulsar respectively. While A1 has shown excess of $>2\sigma$ in all the three mini-runs, there is a non-significant excess only in the first mini-run in A2. The total number of excess events in the first phase bin from data at A2 is only seven when the average was 182 events per phase bin.

The array at site B had a higher energy threshold and since the photomultiplier pulses at site A were digitized, one can check whether the response at site B is commensurate with the energy spectrum of events at site A. From matching the ADC response with the number of events from site B, one can pick out the higher energy events. Figs 2*c* and 2*d* show the behaviour of higher energy events in the array A1 at site A and of all events at site B. In the first two mini-runs, the response of the two arrays is quite similar: 79 events were observed in the first phase bin at each of the two arrays when the average number of events per phase bin is 64. However, the array at site B seems to be deficient in the third mini-run. Therefore, we can only say that the two arrays have behaved similarly for at least 2/3 of the duration. We note that the trigger rates and chance coincidence rates at the two arrays did not show any significant increase during these 15 min.

The Poissonian probability that an excess of 72 or more events is seen when the average is 193, amounts to 6.1×10^{-7}. However, there were 206 independent 15-min intervals and each one was made up of three mini-runs of five minutes. Therefore, the probability has to be multiplied by 618, which is the total number of ways in which the 15 min intervals could be formed. Thus,

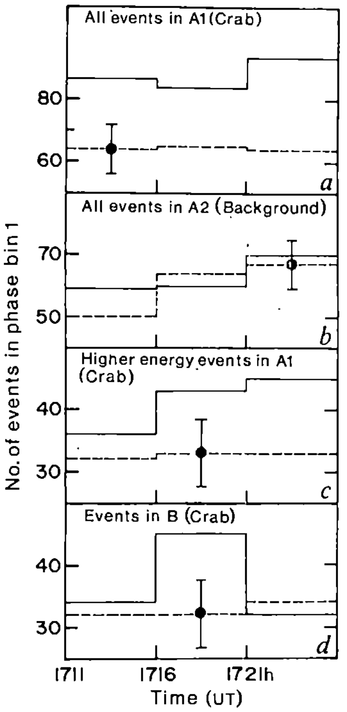

Fig. 2 Solid lines are the observed number of events in the phase bin 1 (0. to 0.05 in phase) during a 15 m interval 1711 to 1726 h (UT) on 23 January 1985 and the broken lines are the average per bin based on the full phasogram. Typical 1σ error bars are shown in each case. *a* Events in the array looking at Crab at site A. *b* Events in the array looking at a point 8°, south of Crab. *c* Higher energy events in the array looking at Crab at site A—the cut was made on energy such that the event rate matches with the one at site B. *d* All events in the array looking at Crab at site B.

the Poissonian probability that the peak is at the position of the radio main pulse due to chance turns out to be 3.8×10^{-4}. A more, conservative estimate for the same is obtained by O'Mongain's likelihood analysis[6] which is 4.2×10^{-3}. At this juncture, one has to ask about the similarity of VHE γ-ray phenomena with those seen by the COS-B (7) group at lower energies from the Crab pulsar. As some of the analyses of the VHE γ-ray observations did not have absolute phase information, it is not possible to say at what phase the signal was seen whenever a claim was made. In some cases, absolute phase information was available (for example, see ref. 1), but the phase of the VHE gamma ray signal did not coincide with that of the signal at lower energies. Therefore, if we accept that there could be phase differences between γ-ray emissions at different energies, one has to multiply the above probabilities by the number of bins which is 20. Therefore, the probability that the signal could appear in any bin due to chance is 7.6×10^{-3} (Poissonian). Thus, the confidence level for a VHE γ-ray signal in our data is 92% (O'Mongain) and 99.2% (Poissonian).

We have tried to verify the authenticity of the signal seen by us by changing the true Crab pulsar period in steps of $\Delta P = 10^{-7}$ s and computing the phasograms for each period. The step size of ΔP is chosen such that the neighbouring trials are independent of each other. 10,000 different periods were tried with 5,000 on either side of the true period; there was not even one trial in which a signal $>5\sigma$ was seen. The probability of seeing a $>5\sigma$ signal in any phase bin is therefore $<6.9/10{,}000 = 6.9\times10^{-4}$ with 99.9% confidence level which is much higher than the value of 92% derived from the likelihood analysis of O'Mongain. The latter may therefore be considered very conservative.

As noted earlier, two such 15-min bursts were seen by Gibson *et al.* in October 1981. The similarities between those and the present burst are that the duration is 15 min and the excess number of events is 70. Whereas the Durham observations did not have absolute phase information and the pulse had a long duration of 6 ms FWHM (full width at half maximum), the peak seen by us coincides with the radio main pulse. The pulse width of the peak in our data is <2 ms consistent with lower energy signals[7]. Finally, Gibson *et al.* saw a $18\pm7\%$ increase in the trigger rate during a 15-min interval on 23 October 1981. The increase in trigger rate of our array A1 was $5\pm4\%$, consistent with no increase. This particular burst seen by us was potentially observable only in those experiments operating from sites in the longitude range 30° E to 105° E during the time 1711 h to 1726 h on 23 January 1985. The time-averaged flux of γ-rays in the burst at site A over its duration of 15 min is calculated to be $(2.5\pm0.6)\times10^{-10}$ γ per cm^2 s^{-1} at $E_\gamma > 1.2$ TeV. The Durham group[2] reported a flux of $(2.0\pm0.3)\times10^{-10}$ γ per cm^2 s^{-1} at $E_\gamma >$ 3 TeV. They considered 34% of their events to be periodic. It appears that the phenomenon of transient pulsed emission occurs only very rarely. Neither Dowthwaite *et al.*[8] nor ourselves saw any more occurrences in observation times of 100 h each. There may also be a persistent weak pulsed emission from the Crab pulsar at the radio main phase[8].

Our conclusion that we are seeing a genuine pulsed emission from the Crab pulsar lasting for 15 min during the night of 23 January 1985 is strongly supported by the presence of a 5.1σ signal in one of the phase bins of the data from an array looking at the Crab pulsar; the absence of any signal in the data from an array looking simultaneously at background; the simultaneous presence of a signal in the same phase bin from an array situated 11 km away and looking at the pulsar; and the failure to obtain a 5σ peak in any phase bin when the same data were analysed in an identical fashion using 10,000 wrong periods. The fact that the signal is seen at the radio main phase shows that at least some of the VHE γ-ray phenomena stem from the same hot spot governing the lower energy processes.

We thank A. R. Apte, N. V. Gopalakrishnan, R. Mahalingam, S. Swaminathan and M. Venkateshwarlu for help in running the experiment; S. C. Tonwar for assistance with data at site B and A. G. Lyne for supplying pulsar elements.

Solar ellipticity fluctuations yield no evidence of *g*-modes

J. R. Kuhn*, K. G. Libbrecht† & R. H. Dicke*

* Joseph Henry Laboratories, Princeton University, Princeton, New Jersey 08544, USA
† Solar Astronomy 264-33, California Institute of Technology, Pasadena, California 91125, USA

Although there have been several claims for the detection of solar *g*-modes with periods between 2 and 10 hours[1-3] and although the present sensitivity of the Princeton Solar Distortion Telescope should allow these low frequency modes to be observed, solar oblateness data from the summers of 1983 and 1984 show no evidence of such oscillations with periods between 1 and 5 hours. In about 250 days (nearly 1,000 hours) of observations, we find no evidence for significant spectral power associated with *g*-modes. In particular, there is no evidence of a 160.01-min period solar oscillation.

The surface velocity amplitudes of solar *g*-modes appear to be between 0.1 and 1 m s^{-1}, but there is little agreement between

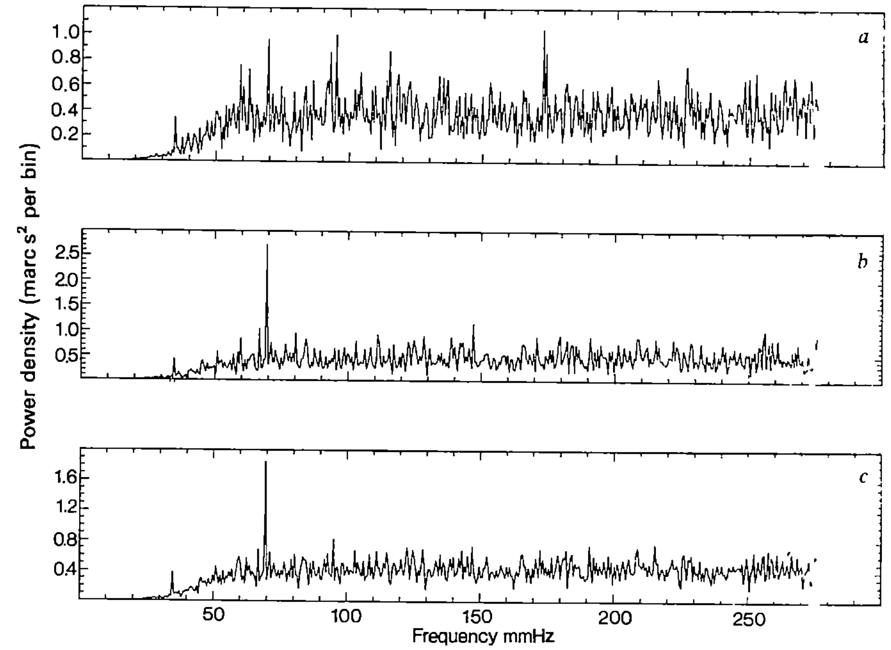

Fig. 1 *a*, Average of the least-squares spectra from the six 1983 data sets. *b*, Same as *a* but for 1984 datasets. *c*, All 12 spectra averaged from 1983 and 1984.

different observers on the excitation spectrum. Several groups have, however, claimed detection of a 160.01-min period solar oscillation[4,5] also with a velocity amplitude that seems to vary between 0.17 and near 1 m s^{-1}. All of these modes have been observed with low spatial resolution and are most probably of low spherical harmonic degree ($l \leq 2$).

It is notable that the surface amplitudes of these oscillations are comparable to 5-min *p*-mode amplitudes of about 15 cm s^{-1} (ref. 6). If the observations are correct, the energy per *g*-mode is roughly 10^8 times larger than typical *p*-mode energies, and is thus of considerable interest.

Except for the ACRIM data[3] and Hill's data[7] most of the low frequency data are due to Doppler velocity observations. Since the period of the modes discussed in this paper are long compared to a radiative relaxation time at the photosphere ($\sim 10^3$ s) the pressure density perturbations due to the oscillation will be nearly isothermal. It is therefore reasonable to calculate the shape change by following photospheric brightness contours as they move due to mass motion of the oscillation displacement field below the photosphere.

The distortion telescope and oblateness data have been described in detail elsewhere[8-10]. In brief, measurements of the deviation from a circular solar limb shape are obtained by measuring the flux from a solar image occulted by a slightly undersize circular occulting disk. The solar flux is measured in two broadband colours (0.5 μm and 0.8 μm) and at 256 positions around the limb. Between 9 and 20 arc seconds of the limb extends beyond the occulting disk. The data are obtained with a specialized telescope now operating at the Mount Wilson Observatory.

A data set at one of three possible limb exposures and two simultaneous colours is obtained approximately once every 5 min. The flux measurements in 128 distinct position angles (only symmetric distortions about the image centre may be observed) around the image are reduced to a displacement in arcseconds using a geometrical calibration. Corrections for optical imperfections of the telescope, mirror distortions, atmospheric transparancy and refraction and facular contamination are applied to the data before obtaining the two coefficients that describe the oblateness of the solar image. For the discussion below the oblateness is described by the coefficients *D* and *V* of a fit of $D \sin 2\theta + V \cos 2\theta$ to the binned shape data. Here θ measures the angle from the solar rotation axis projected onto the image plane (and the *V* and *D* coefficients determine the shape and orientation of the solar oblateness in a frame fixed with respect to the telescope). Thus each observation at a given limb exposure yields four coefficients—a *V* and *D* term for each of the two colour bands. Except for additional atmospheric corrections described by Dicke *et al.*[11] the analysis sketched above essentially follows the description in the references.

The two summers of observations yielded about 254 useful days of data, amounting to about 11,000 5-min observations distributed between the three possible limb exposures. After subtracting least-squares fitted daily quadratic polynomials, to remove daily trends, the standard deviation of the residuals was approximately 24 milliarcseconds in *D* or *V*. The oblateness data will not be sensitive to $l = 0$ or 1 oscillations, but *g*-modes with $l = 2, 3, \ldots$ will contribute to the observed power in the *V* or *D* coefficients. If the 160 min mode is, for example, an $l = 2$ *g*-mode, it will also contribute to the shape data.

For definiteness we will estimate the expected shape signal amplitude from the assumption that the 160 min mode is an $n = 9$, $l = 2$ *g*-mode (the closest predicted frequency for low order modes). The velocity amplitude of an $m = 0$ mode can be written

$$\vec{V}_n(r, \theta) = V_n(r) P_2(\cos\theta)\hat{r} + \frac{U_r(r)}{r}\frac{\partial P_2(\cos\theta)}{\partial\theta}\hat{\theta} \qquad (1)$$

A model calculation[12] gives for the $n = 9$ mode $V_9(R_{\text{sun}})/U_9(R_{\text{sun}}) = 1.14$. The line-of-sight velocity V_{0n} can be related to the modal amplitude V_n from

$$V_{0n} = S_n \cdot V_n \qquad (2)$$

where V_{0n} is the intensity weighted line-of-sight velocity, $\vec{V}_n \cdot \hat{z}$, integrated over the solar disk. The factor S_n is easily evaluated for full disk observations and has been tabulated[13]. For example, $S_9 = 1.3$ for the radial-transverse velocity ratio given above for the $n = 9$, $l = 2$ mode. Other long period $l = 2$ modes have values of S_n within about 50% of this value. Projecting the P_2 (cos θ) term against sin 2θ or cos 2θ gives an approximate relation between the coefficient *V* and the observed full disk velocity amplitude, V_0 of a *g*-mode of frequency ω,

$$V \cong 1.3\ V_0/\omega \qquad (3)$$

Thus, from the 160 min mode with an observed amplitude of about 1 m s^{-1} we expect an oblateness coefficient of $V \sim 2 \times 10^3\ m = 2.7$ milliarcsec. If the oblateness residials were uncorrelated such an oscillating shape signal would be observable with high signal-to-noise.

Below we address two questions: is there evidence of a 160.01-

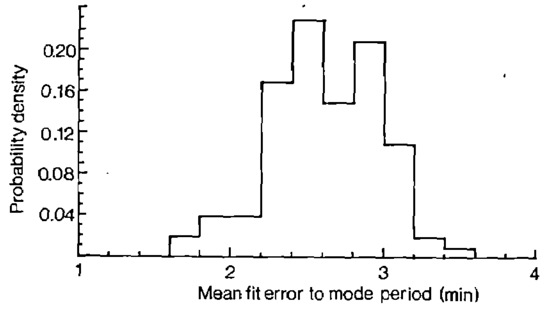

Fig. 2 Distribution of the mean fit errors to the g-mode asymptotic period relation from 100 synthetic peak lists.

min solar oscillation in these data? and is there evidence of any other solar oscillating power in the oblateness residuals? These questions are complicated by the very uneven sampling in time of the data. For example, in 1984 there were about 5,500 observations between day number 107 and 274, spaced at about 5-min intervals. Any mode structure will be aliased in the observed power estimates.

Data from the two colour channels are obtained simultaneously and are highly correlated. Thus to reduce the noise the colours are averaged before computing power spectra. By averaging the power spectrum from three possible limb exposures and both *V* and *D* coefficients we may hope to find a 160-min signal. This has been done in Fig. 1 for 1983 and 1984 data separately, and combined. 'Power spectra' are computed from the summed squared amplitude of least-squares fits of sin ωt and cos ωt to the colour averaged residuals.

Figure 1*c* is an average of 12 'pseudo-spectra' and is our first approximation to the actual mean power spectrum. We note that at frequencies near 104.16 μHz ($T = 160.01$ min) all peaks are smaller than twice the mean power level. To the extent that this approximates the actual mean spectrum the probability distributions of signal in the presence of noise calculated by Groth[14] are applicable here. We find that there is less than a 1% chance that the signal power at $f = 104.16$ μHz is larger than the mean noise power of about 0.4 milliarc². It is notable that there are prominent peaks in the averaged and yearly spectra at periods of 1/10, 1/9, 1/6, 1/5 and 1/3 days. Some 1 per day frequency sidelobes of the stronger peaks are also prominent.

Since we know the frequency and phase of the 160.01-min signal we can also fit for it directly in the data. To simplify the analysis the data were again averaged by colour and limb exposure and binned in half-hour intervals to obtain a single time series for each *V* and *D* coefficient for each year. phase and period described by Grec *et al.*[15] have been usec find the 160-min amplitude and fit error for 1983, 1984 combined datasets, displayed in Table 1. The results of a n linear fit with frequency treated as an adjustable parameter also displayed.

Only the *V* coefficient of the 1984 data shows a statistic significant amplitude at about the 2σ level, but even thi probably due to the nearby strong peak at a period of 159.90 n The results in Table 1 provide no evidence for the 160.01- oscillation with an amplitude greater than, approximately, fit uncertainty of 0.4 milliarcsec.

Several approaches have been considered to look for ot discrete frequency power contributions to the data. (The f technique we examined was used originally by Scherrer[1] finding *g*-modes, and as we will show below is not effective

Scherrer[1] claimed detection of *g*-modes by searching for pe in the Stanford data using an iterative least-squares fitting te nique (the 'clean' algorithm) and then noted that the peaks the asymptotic expression for the mode periods, $T(n, l)$:

$$T = T_0(n + l/2 - 1/4)\sqrt{l(l+1)}$$

where *n* and *l* are chosen separately for each mode to best the observed periods using a single value of T_0. With 14 po spectrum peaks with periods between 172 and 329 min Scher found a good fit with $T_0 = 38.6$ min and *l* and *n* values betwe 1 and 2, and 6 and 20. As a test of the uniquess of such a we have simulated this procedure on 100 sets of random numb evenly distributed in frequency between the corresponding lin ing periods in Scherrer's data. Each set of 14 'peaks' is used estimate a value of T_0 which minimizes the summed squa deviation of the period calculated from equation (4) and rand peaks. The integer *n* and *l* values are constrained to be less th or equal to 25 and 2 respectively and are adjusted to minim the error for each trial T_0 value. A 1% resolution search betwe 30 and 50 minutes finds a value of T_0 which minimizes t summed error. The 100 trials yielded the mean error distributio shown in Fig. 2. Notice that such a fit is not very conclusi since an r.m.s. error of about 3 min is often possible given t range of available parameters. From Scherrer's *n*, *l* and T_0 valu we calculated an r.m.s. value of 3.0 min from his data. Thus fit for T_0 provides no supporting evidence that the power sp trum peaks are of solar origin.

The second approach we tried for finding discrete po contributions was to reduce the aliased structure in the spectr by deconvolving the window function from the observed pow spectra. For this purpose the data were averaged over the thr

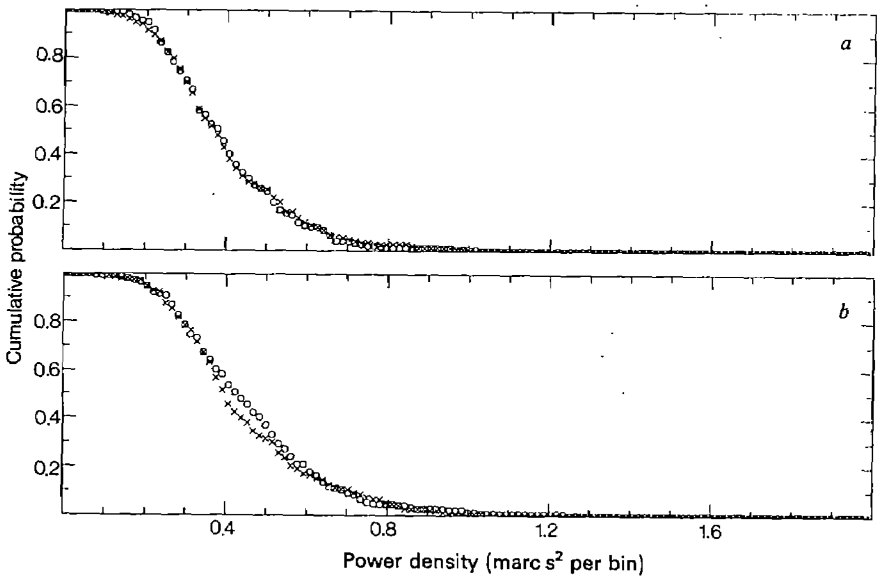

Fig. 3 *a*, Cumulative power distribution of the data in Fig. 1*a* (crosses) and the spectra of normally distributed white noise (circles). *b*, Same as *a*, except for 1984 data and time domain.

Table 1 Least-squares fit for 160.01-min oscillation

		1983	1984	Combined
$f = 104.16\ \mu$Hz				
amplitude	V	0.4 ± 0.5	1.7 ± 0.8	0.3 ± 0.4
(marc s)	D	0.3 ± 0.5	0.6 ± 0.8	0.3 ± 0.4
Frequency (μHz)	V	103.92 ± 0.02	104.23 ± 0.03	104.235 ± 0.003
	D	104.18 ± 0.01	104.00 ± 0.05	104.171 ± 0.003
Amplitude	V	1.3 ± 1.3	2.1 ± 2.0	1.7 ± 0.8
(marc s)	D	1.8 ± 1.3	1.3 ± 1.9	1.4 ± 0.8

limb exposures and two colours and binned in half-hour intervals. Under these conditions the 'filling factor' on the evenly spaced half-hour domain increases to 23% in 1983 and somewhat less in 1984. The technique we applied to work around the gaps is described by Kuhn[16,17]. By choosing a particular set of evenly spaced frequencies the window function effects can be minimized (the 'swap' technique). Unfortunately, numerical experiments on synthetic data with this domain could not be completely 'dealiased' and we've concluded that the domain is too sparse for this method (and probably any other). We finally settled on the statistical approach, described below, to search for g-modes.

We take as a null hypothesis that the 1983 and 1984 power spectra (Fig. 1) are the result of random uncorrelated normally distributed noise. If this is correct then the distribution of power from both years should be consistent with the power distribution generated from noise analysed in the same way as the data. Thus we generate fake data sets on the same domain as the actual data. The values are distributed normally from a distribution whose variance is scaled so that the mean fake power and actual power agree. The resulting cumulative power probability distributions are plotted in Fig. 3. The agreement is quite good if the anamolous peak at 1/6 day period in the 1984 data is ignored. The Kolmogorov-Smirnov test yields a useful quantitative description of the probability that both samples came from the same parent distribution. The K-S test is essentially a measure of the largest deviation between the two distributions[18]. Applying the test to the 1983 and 1984 data separately yields statistic values of 0.34 and 0.86 respectively, indicating that we should accept the null hypothesis. In short, we find no evidence of solar g-modes in oblateness power spectra of mean noise 0.4 milliarcsec^2.

Further, if the previously detected 160.01-min periodic signal is interpreted as evidence of an $l = 2$ g-mode then its amplitude has decreased from near 1 to 0.1 m s^{-1} since its detection in 1974. Unless a hitherto unknown damping mechanism is postulated this is inconsistent with the expected mode damping time of ~40,000 yr[12]. We believe it is more likely that the 160.01-min signal is not due to a solar g-mode.

Here we report preliminary palaeomagnetic evidence from dolerite dykes on West Falkland which suggests that the Falkland Islands were rotated through ~120° during the early stages of the break-up and dispersal of the southern part of Gondwanaland. The rotation itself, and evidence of palaeolatitude, confirm the proposal made by Adie[1] in 1952 that the islands were formerly situated adjacent to the Transkei area of South Africa, where they formed the south-east corner of the Karoo basin with its adjoining Palaeozoic fold belts. The first stage of continental drift probably took place during the Jurassic, as Antarctica separated from southern Africa, the islands moving as a microplate to a position approximately 500 km south-east of present-day Cape Town. Subsequently, during the opening of the South Atlantic, the islands and the Falklands Plateau have drifted to their present position and undergone a further rotation of ~60°.

Figure 1 outlines the geology of the Falkland Islands, and the inset shows the position they occupied before the opening of the South Atlantic in the Lower Cretaceous. This position is obtained by closing the South Atlantic by an anticlockwise rotation of the South American plate through 56.40° about a Euler pole at 46.75° N, 32.65° W, keeping the African plate fixed[2]. This is one of the more straightforward plate tectonic reconstructions which is constrained by a wealth of geophysical and bathymetric data, seafloor magnetic anomalies, the orientation of transform faults and the geometrical fit of the opposing continental shelves of South America and Africa[3,4].

Table 1 Palaeomagnetic results

Sample code	Dyke	n	R	k	α_{95}	Dec.	Inc.

Fig. 1 Geological map of the Falkland Island, after Greenway[17]. For purposes of comparison with South African geology, note that the Lafonian Supergroup correlates broadly with the Karoo, while the Port Stanley Beds, Fox Bay Beds and Port Stephens Beds correlate broadly with the South African units Witteberg, Bokkeveld and Table Mountain sandstone of the Cape Supergroup. Inset, position of the Falkland Islands and Falkland Plateau before the opening of the South Atlantic (Lower Cretaceous) (based mainly on Martin *et al.*[2]). The solid line marks the edge of the south American continental shelf; the dotted line marks that of South Africa. Asterisk shows the position of DSDP site 330 (ref. 14).

Nevertheless, before the development of plate tectonic theory, geologists sought to position the islands in reconstructions of Gondwanaland so that the main geological features matched those of neighbouring continents. For example, du Toit[5] placed the islands to the west of Cape Town, in order to achieve continuity of the east-west fold belts of the Cape, Port Stanley and northern West Falkland in the Falklands and of the Sierra de la Ventana in Argentina. Adie's suggestion[1] that the islands had previously been situated at the east end of the Cape fold belt (the Zwartberg fold belt), offshore from present-day Transkei (Fig. 2), provided near-perfect correlation of Falklands and South African geological features by rotating the islands through 180° from north to south; he cited transport directions in the Dwyka and Lafonian diamictites (with movement from south to north in the Falklands) in support of the postulated rotation. Adie's reconstruction juxtaposes the 1,000-Myr-Natal basement[6] and the Cape Meredith Complex in the Falkland Islands, which is of a similar age[7]; it also removes a problem inherent in the du Toit reconstruction by achieving continuity of the Karoo strata. The Adie reconstruction is much favoured by geological correlations but its validity depends on whether a substantial rotation of the Falkland Islands can be demonstrated.

During a field study in January 1985, C.M. and K.G.C. collected a number of magnetically orientated samples, which comprised 10 hypersthene-bearing dolerites from four different north-south-trending dykes and four baked shales adjacent to a large olivine-bearing east-west dyke, of which, however, no *in situ* exposures were found. All specimens were collected in the area between Fox Bay and Queen Charlotte Bay in West Falkland (Fig. 1). The dykes have usually been assumed to be of the same age as the Karoo dolerites of South Africa; the one published age-determination[8], from a dyke near Cape Meredith, yields a typical Karoo age (Lower Jurassic) of 192±10 Myr by the K-Ar method. Each of our specimens provided a minimum of five 9-mm cylindrical samples for measurement, using the automated SQUID magnetometer at Cardiff[9].

Most samples were demagnetized using alternating fields (AF), but a few were subjected to thermal demagnetization. The results were analysed by means of orthogonal and stereonet plots combined with principal-component analysis[10]. All 10 dolerite samples yielded stable coherent within-sample directions, but two samples (F41 and F31) clearly deviate from the mean of the others (Table 1). These two anomalous results may represent either poor orientation of the samples or the genuine recording of an intermediate geomagnetic field direction. The characteristic direction is generally stable in the range 15-70 mT, with randomly directed low-coercivity components removed on treatment to 15-20 mT, except samples F30 and F32 which were relatively unstable to both AF and thermal demagnetization, compared with the other samples. The AF demagnetization

Fig. 2 Proposed reconstruction of the Falkland Islands relative to South Africa in the Lower Jurassic. This reconstruction is essentially similar to that of Aidie (see Fig. 2 of ref. 1). Palaeolatitude lines are based on McElhinny *et al.*[11]. △, Sites from which palaeomagnetic data for Karoo dolerites were obtained.

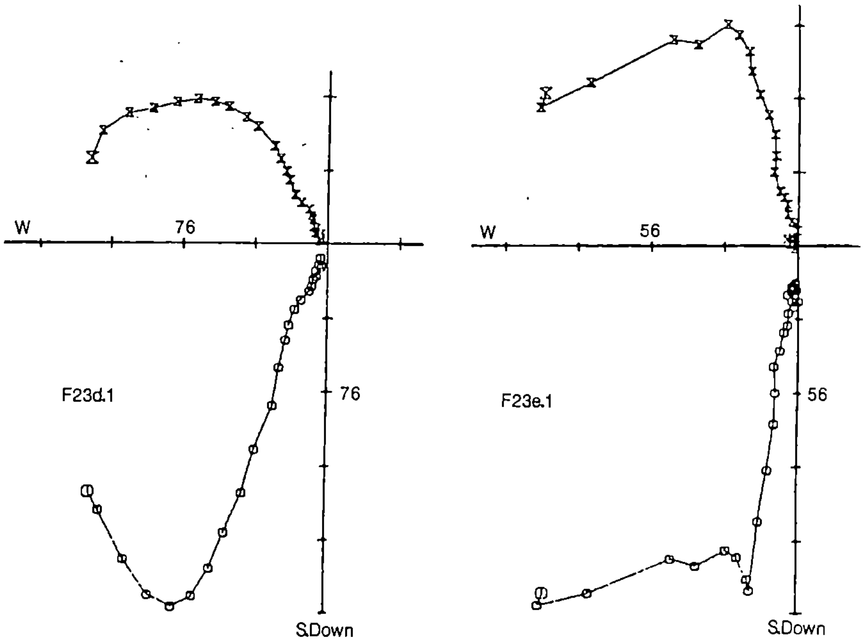

Fig. 3 Orthogonal demagnetization diagrams for two specimens from sample F23. Units for the axes are 10^{-3} Am^{-1}. ×, Horizontal projection; ○, Vertical up-down/east-west projection. Demagnetization steps are in 2.5 mT. See text for discussion.

ehaviour of two specimens from sample F23, a hypersthene-earing north-south dyke, is illustrated in Fig. 3. These two pecimens demonstrate the normal range of within-sample variaility; in specimen F23d.1 there is overlap of the low-coercivity omponents, typical of most specimens, while in F23e.1 these omponents are discrete. In both cases the characteristic direcion of the high-coercivity component is readily isolated.

Three of the four baked sediment samples have specimen otal NRM (natural remanent magnetism) intensities of $<1.5\times$ 0^{-9} A m^{2} kg^{-1} which are unstable to demagnetization, although amples F47 and F45 do yield poorly defined total NRM directions. Sample F46, however, has specimen total NRM intensities f 2-5 × 10^{-8} A m^{2} kg^{-1} which are stable to AF demagnetization. he AF demagnetization characteristics and thermal stability p to 550-580 °C suggest titanomagnetite as the main magnetic hase present in all samples.

The antiparallel nature of the directions for the dolerites ersus the baked sediments (F46, supported by F47 and F45) s indicative of a polarity change between emplacement of the orth-south and east-west dykes. The sample mean direction yields an *equatorial* pole position, and this is inconsistent with any data from southern Gondwanaland in Jurassic times. A rotation by a total of 180 ± 10° is needed to produce a palaeo-pole in the expected near-polar position. Further, the palaeolatitude derived from the inclination is 42 ± 6° S, precluding the conventional reconstruction position south of the Cape, which demands a palaeolatitude of ~55 °S. On the other hand, palaeolatitudes derived for southern Africa from Karoo dolerites, admittedly from old and limited data[11] (Fig. 2), suggest a palaeolatitude for the preferred reconstruction position of the Falklands at 47 ± 5° S, which is consistent with our results. However, because of the small number of samples involved, our results are of a provisional nature and will require confirmation by more detailed studies of both Falklands and Transkei dolerites.

Perhaps the most obvious problem with our proposed reconstruction is the mechanism by which the islands have travelled to their present location. All reconstructions of southern Gondwanaland are problematical and authors differ widely in their opinions as to the precise fit. Recent studies[12,13] have indicated that there are several microplates in the area, some of which have experienced complex movements, for example the Ellsworth Mountains in Antarctica. We tentatively suggest that the Falkland Islands formed one such microplate which was rotated through 180° and moved south and west as Antarctica moved southward and away from Africa during the Jurassic. The islands were then carried to their present location by the opening of the South Atlantic from the Lower Cretaceous onwards. However, drilling at site 330 (see Fig. 1) on the Maurice Ewing Bank[14] shows that the easternmost segment of the Falkland Plateau is composed of continental crust. Furthermore, Tarney[14] thought it likely that the whole of the Falkland Plateau was composed of similar continental crust because of petrographical and geochemical similarities to the Cape Meredith Complex. However, the crust drilled at site 330 yields an age of 535 Myr[15] hence cannot be correlated with the 1,000-Myr-old gneisses of the Cape Meredith Complex. Also, more recent geophysical surveys[16] of the Falkland Plateau revealed that the Falkland Plateau Basin, which separates the Maurice Ewing Bank from the main plateau, is floored by oceanic or highly thinned continental crust. Ludwig[16] aligned Mesozoic magnetic anomalies off South Africa with their equivalents just off the Maurice Ewing Bank and found that the bank probably occupied a position closer to the plateau than it does at present. He went on to suggest that the Falkland Plateau Basin may represent a zone of seafloor spreading or stretching and subsidence of continental crust during early rifting of the continents. Therefore, it now seems unlikely that the Falkland Plateau is a simple extension of the South American and South African continental crust, and we suggest that it may be a collage of microplates. If, as might be expected, all the microplates recognized in this area experienced complex motions during the break-up and dispersal of southern Gondwanaland, this may explain why reconstructions of southern Gondwanaland are so problematical.

We thank Dr C. W. M. Swithinbank (British Antarctic Survey) for drawing our attention to the existence of the Falklands dolerites. Thanks are also due to Mr and Mrs A. McMullen for their hospitality at Fox Bay West. Field and laboratory work in Oxford were supported by NERC research grant GR3/5350 and by a travel grant from the Royal Society. NERC grant GR3/3901 supported the development of the super conducting magnetometer used for this work at Cardiff.

Production of ^{10}Be and ^{26}Al by cosmic rays in terrestrial quartz *in situ* and implications for erosion rates

K. Nishiizumi*, D. Lal†, J. Klein‡, R. Middleton‡ & J. R. Arnold*

*Department of Chemistry, B-017, and †Scripps Institute of Oceanography, A-020, University of California, San Diego, La Jolla, California 92093, USA
‡Tandem Accelerator Laboratory, Department of Physics, University of Pennsylvania, Philadelphia, Pennsylvania 19104, USA

We present results of determinations of ^{10}Be (half life = 1.6 Myr) and ^{26}Al (half-life = 0.705 Myr) produced by cosmic rays *in situ* in several terrestrial rock samples exposed at altitudes of 1–4 km. These experiments were designed to determine the feasibility of using quartz extracted from natural surfaces for studying continental weathering/erosion processes[1]. Quartz is attractive as a target material for several reasons. Its low aluminium concentration allows measurement of ^{26}Al after exposures as short as 10^3 yr; its integrity minimizes the possibility of contamination by rain with ^{10}Be produced in the atmosphere; and its ubiquity ensures that it is found in a wide variety of geological settings. However, the cosmic-ray production rates of ^{26}Al and ^{10}Be even at mountain altitudes are low[2,3], only 10–100 atoms g^{-1} yr^{-1}, with the consequence that earlier attempts[4,5] to determine *in situ* produced ^{36}Cl and ^{26}Al in rocks were not continued. Recent development of accelerator mass spectrometry (AMS) however, has made the measurement of 10–20g samples feasible. The results presented here demonstrate the feasibility of quantitatively measuring ^{10}Be and ^{26}Al produced *in situ* by cosmic rays in quartz and the possible applications of ^{10}Be and ^{26}Al as a pair for studying continental weathering/erosion processes.

Table 1 Sample description

Sample	Site	Elevation (m)	Weight of quartz analysed (g)	Al content of quartz (p.p.m.)	Be carrier added (mg)
ALH	Allan Hills, Antarctica	2,050	13.09	467	1.49
Q-1	Anza Borrego, California	1,140	20.22	4.9×10^4	1.37
Q-L	Anza Borrego California	1,200	22.18	100	1.50
KKS-1	Leh, Ladakh	4,000	17.29	52*	1.50
KKS-3	Kinnaur, Himachal Pradesh	3,400	16.39	289	1.50

* Intrinsic Al content of the purified quartz grains; an amount equivalent to 0.53 mg Al was added for AMS measurement.

The rock samples analysed are listed in Table 1. Sample ALH, which is quartzite (determined by thin section), was collected at the peak of Allan Hills, Antarctica (76°42′ S, 150°31′ E), elevation 2,050 m, by one of us (K.N.) during the 1983–84 field season of Antarctic search for meteorites. Allan Hills are located about 230 km north-west of McMurdo station. The large blue ice area (Allan Hills ice field) is stagnated by the Allan Hills. More than 2,000 meteorites have been found on the ice field and contiguous areas during the past 10 yr. At present, the Allan Hills are not covered with ice because of strong winds which prevent net snow accumulation in winter; in summer there is no precipitation. It would be useful to determine when Allan Hills lost their ice sheets. The sample was collected from the surface of a flat-top area, ~200 m north of the glaciological survey station[6]. The Q-1 and Q-L samples were collected from Anza Borrego, California (33°12′ N, 116°27′ W), ~100 km east of San Diego by A. E. Engel and us. The samples were collected from the flat tops of large rocks (~5 m in diameter) located at elevations of 1,140 m (Q-1) and 1,200 m (Q-L). The ^{40}K-^{40}Ar age of the Borrego rocks is ~90 Myr. Sample KKS-1 was collected from a quartz vein intruding Indus Flysch near Kiari, Kashmir, India (34° N, 78° E), at an elevation of 4,000 m. KKS-3 was collected from quartz-kyanite veins intruding Kyanitesillimanite schists, Himachal Pradesh, India (32° N, 78° E), elevation 3,400 m.

Quartz was extracted from the rocks primarily by using the higher reactivity of feldspars with HF (details will be presented elsewhere). The chemical procedure used for extraction of Be and Al was essentially the same as in previous experiments for meteoritic and lunar samples[7]. The ^{10}Be and ^{26}Al measurements were performed on the University of Pennsylvania FN Tandem Van de Graaff accelerator[8,9].

As the ratio $^{10}Be/^{9}Be$ in commercially available beryllium[10] is $\sim 1\times 10^{-14}$, we prepared a ^{9}Be carrier from a beryl (supplied by B. Dassanacharya). The measured $^{10}Be/^{9}Be$ and $^{26}Al/^{27}Al$ ratios and the ^{10}Be and ^{26}Al concentrations in the quartz samples are shown in Table 2. The $^{10}Be/^{9}Be$ and $^{26}Al/^{27}Al$ ratios of the samples were normalized to standards[7] after blank corrections. Our beryl derived Be carrier has a $^{10}Be/^{9}Be$ ratio $<3\times 10^{-15}$, corresponding to $<2\times 10^{5}$ atoms ^{10}Be/mg Be.

Table 2 shows that the ^{10}Be and ^{26}Al produced *in situ* by cosmic rays can be measured easily in natural quartz samples of 10-20 g size. And, in fact, measurement of ^{26}Al produced *in situ* on Earth is as easy as in extraterrestrial samples if the ^{27}Al concentration is <300 p.p.m.

Figure 1 shows the theoretical saturation values[1] plotted for ^{10}Be and ^{26}Al produced in quartz at the Earth's surface. The ^{10}Be is caused by nuclear spallation of Si and O, and the ^{26}Al is caused by nuclear spallation of ^{28}Si and negative mu-meson capture in ^{28}Si. Other contributions to the production of ^{26}Al and ^{10}Be from *in situ* radioactivity are negligible. The samples KKS-1 and KKS-3 are not surface samples; they were collected from quartz veins to obtain samples with low Al content. Figure 1 shows the ^{10}Be data for the three surface samples. These samples have concentrations lower than secular equilibrium values, corresponding to 2×10^{4}–1.5×10^{6} yr of effective irradiation. As the samples are not at the surface secular-equilibrium concentration value, they must have been shielded by some overburden of material for an appreciable fraction of the flux-integrating period of these isotopes, $\sim 10^{7}$ yr. This overlying material could have been removed either all at once or gradually. If the samples had been covered by a thick ice sheet, a sedimentary deposit, or a layer of rock which was removed during the retreat of a glacier, the time needed to remove this cover could have been short ($<10^{4}$ yr). If the overburden was removed by erosional weathering, the process could have been continuous, and the shielding of these samples could have been reduced gradually. The result is that the concentration of these radionuclides can be used to place upper limits on the rate of erosion (weathering) and lower limits on the amount of time that the samples have not been covered with an appreciable layer of either rock or ice. Such estimates depend on a knowledge of the rates of production of these isotopes, and on the model adopted to explain the exposure history of the samples.

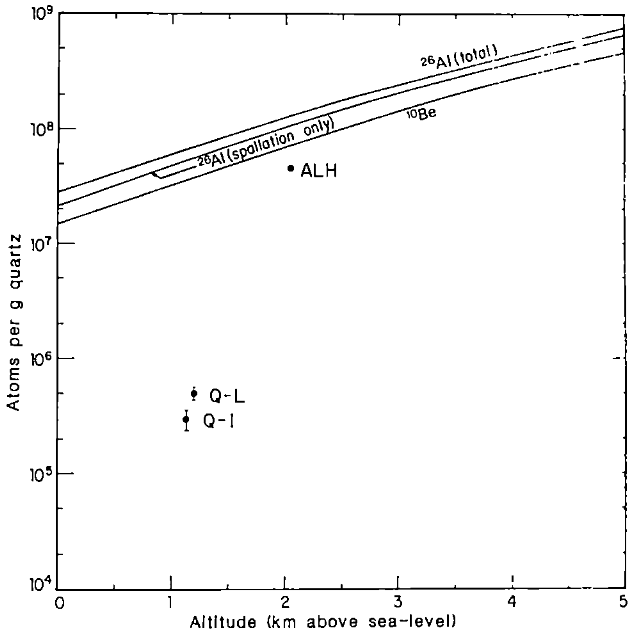

Fig. 1 Theoretically estimated *in situ* saturation values of ^{10}Be and ^{26}Al in quartz, based on production rates in ref. 1. Values are shown as a function of altitude for geomagnetic latitude (50–90°). ^{10}Be is produced in nuclear spallation of Si and O, and ^{26}Al from spallation of Si and negative mu-meson capture of ^{28}Si. The total production rate of ^{26}Al (spallation + capture) is shown as is the measured concentrations of ^{10}Be in three surface exposed rocks.

Next, we briefly consider the expected isotope concentrations in terms of a simple exposure history model which occurs without change in the altitude of the sample. The production rate in the rock, $P(t)$ is time dependent because of change in the rock geometry caused by erosion of overlying ice/sediment. If the production rate of an isotope at the surface of a flat rock is P_0, then the expected production rate $P(x)$ at x cm depth is:

$$P(x) = P_0\, e^{-\rho x/\Lambda} \qquad (1)$$

where Λ is the absorption mean-free-path ($\sim 150\ \mathrm{g\,cm^{-2}}$) and ρ is the density of the rock. If the variation in x with time is known, the production rate at the test point ($x = 0$) for all past times can be calculated. The expected concentration of an isotope C, at the present rock surface is given by:

$$C_{s(x=0)} = \int_0^\infty P(t)\, e^{-\lambda t}\, dt \qquad (2)$$

where λ is the disintegration constant of the isotope; and time, t, is reckoned backwards. For the simple case of a constant

Table 2 Measured ^{10}Be and ^{26}Al concentrations in quartz samples

Sample	$^{10}Be/^{9}Be$ ($\times 10^{-15}$)	^{10}Be (10^{6} atoms g^{-1})	$^{26}Al/^{27}Al$ ($\times 10^{-15}$)	^{26}Al (10^{6} atoms g^{-1})	$^{10}Be/^{26}Al$ (atom ratio)
ALH	$(6.00\pm 0.24)\times 10^{3}$	45.0 ± 1.8	$(1.93\pm 0.19)\times 10^{4}$	201 ± 20	0.224 ± 0.024
Q-1*	65 ± 14	0.29 ± 0.06	—	—	—
Q-L	110 ± 11	0.497 ± 0.050	$(1.48\pm 0.16)\times 10^{3}$	3.31 ± 0.36	0.150 ± 0.022
KKS-1†	14.2 ± 1.7	0.082 ± 0.010	107 ± 19	0.207 ± 0.037	0.396 ± 0.086
KKS-3†‡	4.8 ± 1.9	0.028 ± 0.011	$8.2^{+7.0}_{-4.4}$	$0.054^{+0.052}_{-0.029}$	(0.03–1.0)

* ^{26}Al could not be measured in this sample because of the high intrinsic aluminium content of the sample (see Table 1).

† These are not surface samples (see text); no estimates can be made on their shielding.

‡ The errors cited in the ^{26}Al values are the inverse Poisson estimates for three counts.

erosion ($dx/dt = \varepsilon$) the steady-state isotope concentration is given by:

$$C_{s(x=0)} = P_0/(\lambda + \rho\varepsilon/\Lambda) \qquad (3)$$

Inversion of equation (3) allows the deduction of the model erosion rates assuming that the sample is in secular equilibrium. An estimate based on another isotope of different half-life can be used to validate the erosion model adopted. In favourable cases, the ratio of concentrations of two isotopes can be used to determine the erosion rate, but if $\rho\varepsilon/\Lambda$ is $\leq\lambda$, the ratio can lead to erroneous estimates due to uncertainties in isotope production rates. If ε is too large, then isotopic concentrations are too low to measure. In practice, erosion rates $<10^{-2}$ cm yr^{-1} are easily measurable.

There are several advantages of using ^{10}Be and ^{26}Al, as opposed to ^{36}Cl, in this application. The production of ^{26}Al and ^{10}Be results from spallation of Si and O, the principal constituents of quartz. The production of ^{36}Cl is the result of spallation of several minor constituents, such as Ca, Ti, and the capture of thermal neutrons by ^{35}Cl. Furthermore, some of the chlorine in the rock is in a mobile form and can be exchanged in interactions with seepage water. Consequently, the ^{36}Cl production rates have to be determined for each rock studied. It is unlikely that the mineral phases which are best for the measurement of ^{36}Cl will also be suitable for measurements of ^{26}Al or ^{10}Be. In particular, minerals with sufficient concentration of target materials for the production of ^{36}Cl are unlikely to be low enough in ^{27}Al for ^{26}Al measurement. In addition, minerals with enough Ca and Ti for ^{36}Cl production are often easily altered during weathering, increasing the possibility of contamination from atmospheric sources of ^{10}Be and ^{36}Cl (from the bomb pulse).

We will discuss the implications of the results in Table 2 in view of the above simple steady-state erosional model and the theoretical ^{10}Be, ^{26}Al production rates in quartz, for samples ALH, Q-1 and Q-L only; the shielding depths of the two KKS samples are unknown, so that the absolute concentrations of ^{10}Be and ^{26}Al in terms of erosion rates cannot be considered.

The ^{10}Be/^{26}Al production ratios for 1-5 km altitude lie in the range 0.24-0.28 (Fig. 1); the atom ratios ^{10}Be/^{26}Al in rock samples should, therefore, be between 0.25 and 0.5, that is between the ratio at inception of production and the ratio at secular equilibrium. The measured values of the ratio do fall within this range for all samples except Q-L, which is lower than the lowest expected, by a factor of 1.7. The measured ratio in ALH is close to theoretical ratio at production which is surprising considering that the ^{10}Be concentration is high, corresponding to an effective period of irradiation (concentration/production rate at surface) of ~1.5 Myr, and one would expect a value of ~1.3 times the production ratio. The results of ALH and Q samples can be made consistent if one assumes a value for the ^{10}Be/^{26}Al ratio at production of ~0.15-0.17. This would imply either that we[1] overestimated the ^{10}Be production rate or that we underestimated ^{26}Al production by a factor of ~1.5. As the ^{26}Al concentration of the ALH sample is higher than the theoretical value, we probably underestimated the ^{26}Al production. Uncertainties in the estimation of production rates of ^{10}Be and ^{26}Al are at least ±20% and ±30% on the ratio. The disagreement is, therefore, not surprising.

Despite the uncertaintites in production rates, we can obtain fairly meaningful model values of erosion rates, based on the observed concentrations of one of the isotopes. By partial differentiation of equation (3), we obtain:

$$(d\varepsilon/\varepsilon)/(dP_0/P_0) = 1/(1 - \lambda T) \qquad (4)$$

where T is the effective irradiation period, $C_{x=0}/P_0$. Equation (4) shows that estimated rates of erosion are less sensitive to uncertainties in production rates for longer-lived isotopes, that is smaller λT. The effective irradiation periods (T) based on the ^{10}Be concentration for samples Q-1, Q-L and ALH are 1.75×10^4, 2.8×10^4 and 1.3×10^6 yr, respectively. These values correspond to erosion rates of 2.8×10^{-3}, 1.7×10^{-3} and 1.7×10^{-5} cm yr^{-1}. From equation (4), we deduce that a ±30% uncertainty in ^{10}Be production rate will lead to uncertainties of ±30, ±30 and ±68% in the erosion rates in these three cases.

Our results clearly demonstrate the feasibility of measuring ^{10}Be and ^{26}Al in quartz. ^{26}Al determinations require mineral phases low in Al so that the ^{26}Al/^{27}Al ratio is high enough to measure. ^{10}Be studies can be made in any mineral as long as it can be established that it does not absorb rainwater-scavenged atmospheric ^{10}Be, which we designate as the 'garden-variety' ^{10}Be to distinguish it from that produced *in situ*. Once erosional models have been checked by studies of several isotopes (for example, ^{14}C, ^{36}Cl, ^{26}Al, ^{10}Be) measured in the same sample, large-scale synoptic erosional studies of land masses can be made based on ^{10}Be concentrations in abundant suitable rock minerals. These techniques can also be used to measure exposure times in surfaces in which the erosion rate is sufficiently low, or even to date volcanic flows, if suitable mineral phases can be isolated. This approach may therefore be a method of obtaining quantitative data on denudation of rock surfaces, for which no techniques are available.

Our present results show the potential of using ^{10}Be and ^{26}Al produced *in situ* by cosmic rays for quantifying continental erosion rates and other processes; erosion rates are primarily based on estimates of the transport of detrital sediments and dissolved elements to oceans from continental runoff. It is clear that better estimates of the isotope-production rates are needed and checks of erosional history with other isotopes produced by cosmic rays (stable and radioactive) would be helpful.

We thank A. L. Engel and E. L. Winterer for discussions and K. K. Sharma for providing the high-purity quartz samples KKS-1 and KKS-3. We thank F. Kirchner for typing the manuscript. This work was supported by NASA grant NAG 9-33; NSF grant Phy 82-13598, and Cal Space grant CS-04-85.

Thermal erosion by komatiites at Kambalda, Western Australia and the genesis of nickel ores

D. I. Groves*, E. A. Korkiakoski*, N. J. McNaughton*, C. M. Lesher† & A. Cowden‡

* Department of Geology, University of Western Australia, Nedlands 6009, Australia
† Department of Geology, The University of Alabama, University, Alabama 35486, USA
‡ Kambalda Nickel Operations, Western Mining Corporation Ltd, Kambalda 6442, Australia

Huppert *et al.*[1] calculated that komatiites flow turbulently, transfer heat efficiently to their substrate, and thus potentially produce thermal-erosion channels in sequences onto which they were erupted. Their suggestion that komatiite-hosted (Kambalda-type[2]) nickel ores reside in such channels has led to resurgence of interest in volcanic models for ore emplacement[3-5] and caused controversy[6,7]. Such models have important implications, not only to ore-genetic studies but also to interpretation of the geochemistry

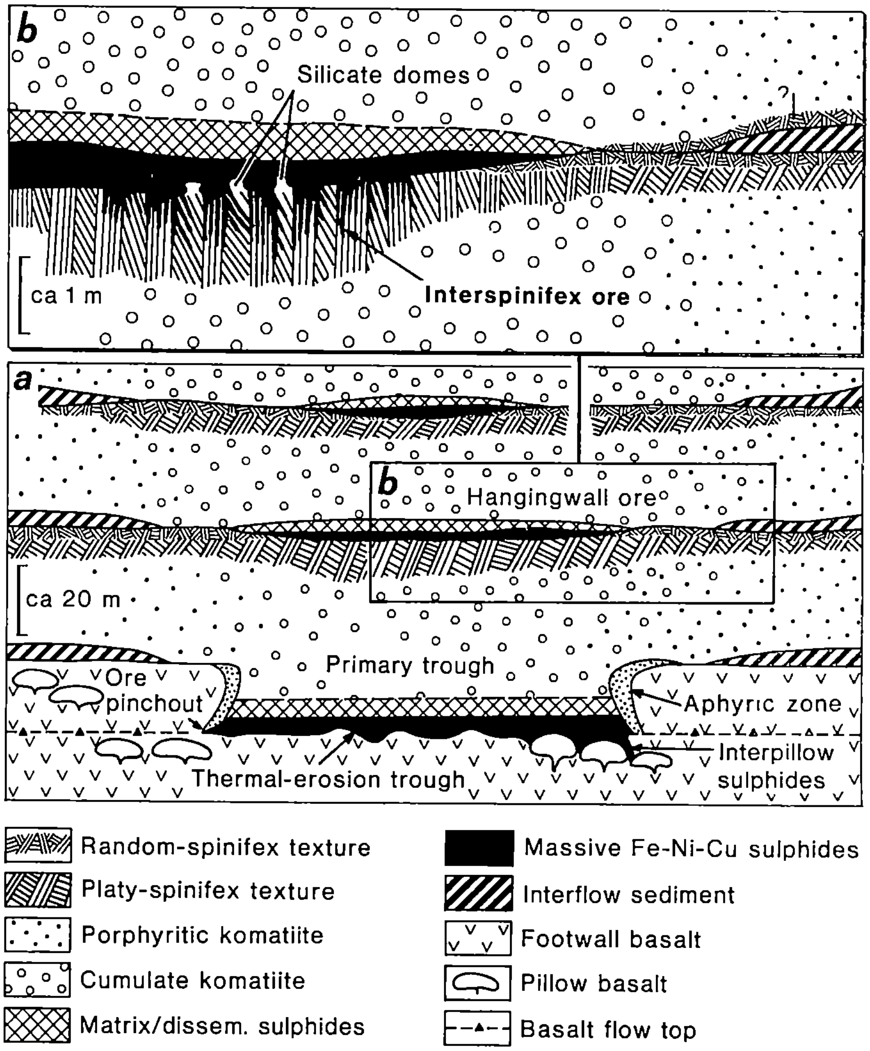

Fig. 1 Schematic representation (not to scale) of: *a*, Relationships in the lower part of the Kambalda komatiite pile emphasizing embayment (trough) structures and showing hangingwall ores (adapted from ref. 23); and *b*, relationships between massive ores, interspinifex ores and komatiite flow-tops at Lunnon Shoot.

of komatiites[8] and their Sm–Nd systematics[9,10]. Here we demonstrate that interspinifex Fe–Ni–Cu sulphide ores, which underlie some hanging wall massive sulphide ores at Kambalda the site of one of the world's major nickel deposits, formed through thermal erosion of underlying komatiite flows and possibly also sediments, providing proof of thermal erosion. However, we caution against the general application of thermal-erosion models to the eruption of komatiites. It seems that significant thermal erosion occurred rarely, and only where basal concentrations of highly thermally conductive sulphide liquid were present at the base of localized lava channels. Isotope data[11,12] and theoretical considerations[13] suggest that the komatiites were contaminated by crustal rocks before eruption, although there is limited evidence that localized contamination, including sulphide assimilation[4], may also have occurred below lava channels localized in pre-existing embayments or troughs.

Despite recent predictions that komatiites cause significant thermal erosion of their substrates[1], there has been no unequivocal supporting field evidence. This has led to suggestions that real komatiites may be less voracious than mathematical counterparts[6]. Therefore, we have tested the models using the well-documented Kambalda nickel deposits[2,3,5]. First, we present evidence for the role of thermal erosion in the formation of very localized interspinifex ores, and then we discuss its wider relevance.

Interspinifex ore is a very minor component of hanging wall ores at Lunnon, Fisher and Hunt Shoots, Kambalda[2]; its situation is shown schematically in Fig. 1. Basically, it comprises Fe–Ni–Cu sulphides interstitial to pseudomorphs after platey olivine spinifex. This ore type occupies shallow depressions in the top of the lowermost flow and is physically contiguous with overlying sulphide ore, which forms the base of the second flow in the komatiite pile. Replacement of original interstitial glass and/or pyroxene by Fe–Ni–Cu sulphides is required by (1) the almost perfect preservation of spinifex texture, and (2) transitions from sulphides to the mesostasis adjacent to pseudomorphs after olivine plates. The best interpretation is that glass and pyroxene in the spinifex-textured top of the lower flow were selectively melted by the overlying sulphide-bearing komatiite flow, and the generated silicate liquid was displaced upwards by the denser sulphide liquid. The critical evidence for such an origin includes: (1) the similarity of chemical compositions (Ni, Cu, Co, PGE) of spinifex-textured ore and overlying massive ore[14]; (2) the occurrence of magmatic ferrochromites in the spinifex-textured ores, and chromite zones on silicate-sulphide interfaces as in magmatic ores[15], (3) the presence of randomly buckled olivine blades, consistent with emplacement of hot sulphide liquid between them, and (4) the occurrence of small chromite-rimmed, silicate-rich domes, consistent with the composition of interpreted segregations of displaced silicate liquid, at the base of overlying massive ore. None of these features is consistent with metamorphic-hydrothermal replacement, the only alternative origin.

Interspinifex ore was formed at temperatures below the olivine liquidus[16] but above the sulphide liquidus[17]. The fact that virtually all interspinifex ore has platy-spinifex texture rather than random-spinifex texture, which typically occurs at the top of komatiite flows at Kambalda[18], suggests thermal erosion of the uppermost part of the underlying flow before formation of the interspinifex ore. Stratigraphical correlations with komatiite-komatiite contacts along strike, combined with measurements of the shallow depressions occupied by interspinifex ore, suggest a maximum of 1 m of erosion of komatiite before formation of that ore (Fig. 1*b*). Thus, a *prima facie* case for thermal erosion is established. The interflow sediment, present along strike, may also have been eroded but there is no direct evidence.

The significance of these observations to the applicability of thermal-erosion models, in general[1,6,7], can be assessed through (1) relationships along strike and down dip from interspinifex ores, and (2) consideration of observational data for more typical basal (contact) ores[2] in combination with accumulated petrological, geochemical and isotopic data from Kambalda komatiites.

Relationships in localized interspinifex ore environments indicate that thermal erosion is virtually restricted to some portions of the contact occupied by massive sulphide ores (Fig. 1). Normally, the upper komatiite flow conformably overlies interflow sulphidic sediments with little evidence for interaction, or directly overlies fine-grained random spinifex-textured komatiite. Thin amphibole-chlorite rich assemblages occur at the base of the upper flow in places[19], and probably represent former chilled margins[18]. Thus field evidence from hanging wall ore-environments at Kambalda indicates that thermal erosion of komatiite occurred locally only where pools of sulphide liquid had already accumulated, presumably caused by the order-of-magnitude higher thermal conductivity of the sulphide liquid[20] relative to komatiite liquid[21,22], and its lower liquidus temperature[17]. There is no definitive evidence to indicate whether the massive sulphides were purely magmatic liquids, or whether their occurrence marks the position of lava channels[4], in which more prolonged throughput of lava was capable of assimilating sulphide sediments and generating sulphide liquid below which thermal erosion of komatiite continued.

Observations on basal ore environments at Kambalda favour a primary volcanic/topographical control on embayments and localized lava channels[23] rather than initial formation by thermal erosion. Interpretation is hindered by subsequent, commonly severe, metamorphic alteration of the ultramafic rocks combined with structural modification[2,23]. Despite this, the komatiites within the lava channels are texturally and geochemically distinct from flanking flows[23], which have conformable contacts with underlying sulphide sediments over >90% of the total contact surface. Komatiites within the lava channels show evidence for prolonged flow-through of magma, not shown by flanking flows. Evidence from Kambalda that confining embayments were primary volcanic features before komatiite eruption includes: (1) stratigraphical control of some embayments whose base (the base of the initial komatiite flow) coincides with the flow top of the penultimate basalt flow[23], (2) the presence of probable aphyric margins on komatiites around some embayments[23], and (3) the elongated form of most major embayments parallel to the interpreted fault-bounded margins of the volcanic basin[24]. The presence of unassimilated or partly assimilated sediments in the similar embayments at Scotia and at Wannaway[3] indicate that those embayments also predate sulphide ore and komatiite emplacement.

Structural and metamorphic modification of ore environments inhibits unequivocal interpretation. However, there are second-order irregularities within major embayments that could possibly be formed by thermal erosion. These include: (1) spaced 1-2 m convex-upward, projections of basalt into massive ore (such as Long and Durkin Shoots)[23]; (2) small elliptical depressions confining Fe-Ni-Cu ores (such as Ken Far East, Juan East); (3) widespread, structurally modified, lateral tongues of massive sulphide in basalts in ore pinchouts (Fig. 1*a*); and (4) interpillow Fe-Ni-Cu sulphides which may well be representative of thermal erosion. The unusual silicate gangue mineralogy of massive ore[25,26] could also be partly caused by melting of basal chills and/or basalt, and preservation of so-formed immiscible silicate melt in sulphides below overlying crystallized olivine cumulates (compare with silicate domes associated with interspinifex ores). These features indicate the possibility that localization of lava channels and basal sulphide liquids in original volcanic/topographical embayments focused thermal erosion and modified the original embayments.

Several lines of evidence suggest that Kambalda komatiites are contaminated; (1) Sm-Nd (refs 9, 10) and Pb-Pb (ref. 12) or U-Pb (ref. 11) isotope studies indicate that Sm-Nd 'isochrons' are mixing lines between komatiites and older crustal components; (2) Pb-Pb studies of iron sulphides from nickel ores and adjacent sulphide sediments suggest mixing of mantle and older crustal lead[27]; (3) the similarity of S/Se ratios and $\delta^{34}S$ values of nickel ores and sulphide sediments[4,25] and anomalously high Zn chromites in mineralized komatiites[15,27]. Several of these geochemical parameters indicate that contamination affected both the basal mineralized komatiite(s) and the entire komatiite pile. These include: (1) the tight grouping of both komatiites and basalts on Sm-Nd mixing lines[6,9]; (2) the occurrence of >3,000 Myr xenocrystic zircons in overlying komatiitic basalts[11]; and (3) chalcophile-element depletion[28] and occurrence of Zn-rich chromites[15] throughout the Kambalda komatiite pile. Collectively, these data suggest that sulphide liquids separated from komatiites that were contaminated during ascent through older continental crust, as predicted theoretically[13]. However, the similarity of S/Se ratios and $\delta^{34}S$ values of nickel ores and adjacent sulphide sediments[4,25] plus the fact that lead isotope compositions of iron-sulphides from nickel ore could represent mixtures of mantle lead and lead from the sulphide sediments[27], suggests that assimilation of sulphide sediments contributed to sulphide liquids in at least some komatiites.

There is unequivocal evidence from hanging wall ore environments at Kambalda for localized, shallow thermal erosion channels in early komatiites (and possibly sediments) underlying subsequent komatiite flows containing basal sulphide liquid pools. Conduction of heat from the overlying turbulently convecting komatiite through the highly thermally conductive sulphides seems to have been the controlling process. In the major basal (contact) ore environments, however, primary major embayments were volcanic/topographical features. There is some evidence for melting of the basalt substrate by thermal erosion only beneath sulphide-liquid pools at the base of lava channels confined by the embayments. Some sulphide liquid probably formed as a result of initial thermal erosion of sulphidic sediments. Such assimilation can explain some of the contamination shown by komatiites, but other parameters suggest contamination during magma ascent. Our study suggests that komatiites were erosive, but were more lethargic than previously suggested. It stresses the role of highly conductive sulphides, associated with lava channels, in thermal erosion of komatiitic and basaltic substrates by komatiite lavas.

We thank J. J. Gresham of Kambalda Nickel Operations for access to the Kambalda deposits, and several other Kambalda geologists for documentation and discussions of Kambalda geology. We also acknowledge UWA colleagues, particularly N. Dahl and P. Parker, and CSIRO staff, especially R. E. T. Hill, for useful discussions. E.K. was sponsored by the Australia-European Awards Programme and partly funded by Kambalda Nickel Operations.

Estimating the error of age interpolation in sedimentary rocks

Catherine Badgley*, Lisa Tauxe† & Fred L. Bookstein‡

Magnetostratigraphic data can provide information on rates of sediment accumulation within a single sedimentation system over time spans from 10^4 to 10^6 yr. The short-term rate of sediment deposition varies with time; the apparent average rate over any longer interval also depends on the relative durations of periods of deposition, stasis (non-deposition), and erosion. While the average rate can be used to infer the time of occurrence of an event from its stratigraphical position, the inferred age has an uncertainty deriving from the variability in rate of sediment accumulation over all shorter timescales. We analyse here variability in sediment accumulation rates provided by the magnetostratigraphy of Miocene, Siwalik sediments from Pakistan. For long periods ($>10^6$ yr), sediment accumulation is approximately linear through time. Over short intervals (10^4–10^5 yr), however, there is considerable variability. To provide an error term for an absolute age interpolated between boundaries of polarity units, we use a resampling technique similar to the statistician's 'bootstrapping'. We illustrate this approach by estimating a standard error for the interpolated age of a biostratigraphical datum: the first appearance of hipparionine equids in the Siwalik sequence near the town of Khaur. The first appearance of "*Hipparion*" in the Khaur sequence is 9.22 ± 0.09 Myr.

The assignment of absolute age estimates to sedimentary rocks requires either horizons susceptible to radiometric dating or access to the geomagnetic reversal timescale (GRTS). Fossils may indicate relative chronology in sedimentary rocks but do not convey information about absolute age. Thus, stratigraphical sections usually contain an arbitrary scatter of levels from which age information is available. Ages of all other levels are estimated indirectly by linear interpolation between levels of more accurately known age.

Linear interpolation of an estimated age within a stratigraphical section assumes that the sediment accumulation rate calculated for the longer, dated portion of the sequence also applies to much shorter time intervals. This is rarely the case. Unless sediment accumulates continuously and without erosion, sediment accumulation rate decreases as the time span of measurement is increased[1-3]. Thus it is necessary to consider when linear interpolation of an age estimate is justified, and how to assess the accuracy of the age estimate. Sadler[2] proposed replacing an interpolated age value by an age range based on an estimated incompleteness of the section. The completeness estimates[2,4] are based on the pattern of sediment accumulation rate versus time span for a large compilation of data from one class of sedimentary environments, such as fluvial systems. There is, however, no particular reason why any such variance should usefully model the variance within a sedimentation system.

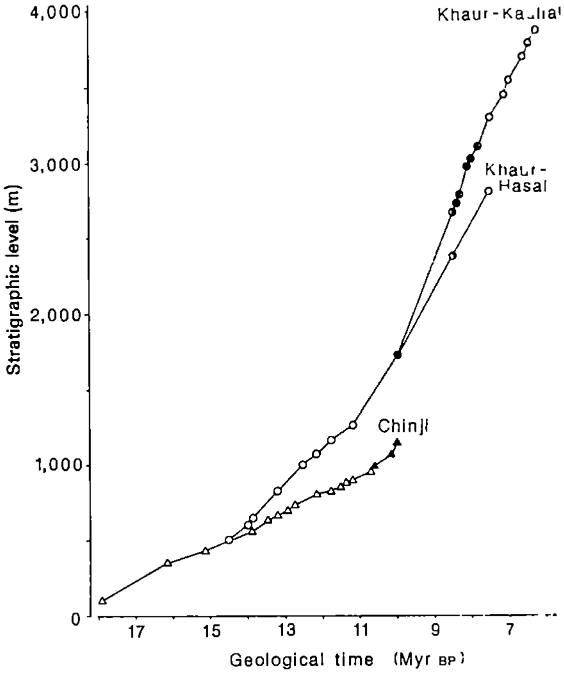

Fig. 1 Cumulative stratigraphic thickness over time in Siwalik sediments of northern Pakistan. Chinji and Khaur are two geographical areas in the same depositional system; Kaulial and Hasal are local section names[5]. Each data point demarcates a reversal of magnetic polarity. Triangles represent data from the Chinji area and circles data from the Khaur area. Solid symbols, strata older than 11 Myr; open symbols, strata younger than 11 Myr. A change in sediment accumulation rate occurred between 10 and 11 Myr, as indicated by the change in slope. Net sediment accumulation appears to be linear through time for the Chinji data older than 11 Myr and for the Khaur data younger than 11 Myr.

A more direct approach is to exploit observable variability of sediment accumulation rates within a sedimentation system to build a statistical description of the relationship between sediment accumulation and time. The problem in age interpolation is how to estimate the proportion of time span present in a known proportion of sediment thickness from the interval of interpolation. One way to assess the standard error of such ages is to document this variability using intervals of a similar length for which age is not interpolated but is rather observed. Long magnetostratigraphic sections provide independent measurements of sediment accumulation rate for every discernible magnetic polarity interval. We demonstrate a method of 'resampling' a magnetostratigraphic section to generate multiple intervals that can be divided into shorter intervals of known time span and thickness. The original and resampled data together provide an estimate of the standard error about an interpolated age.

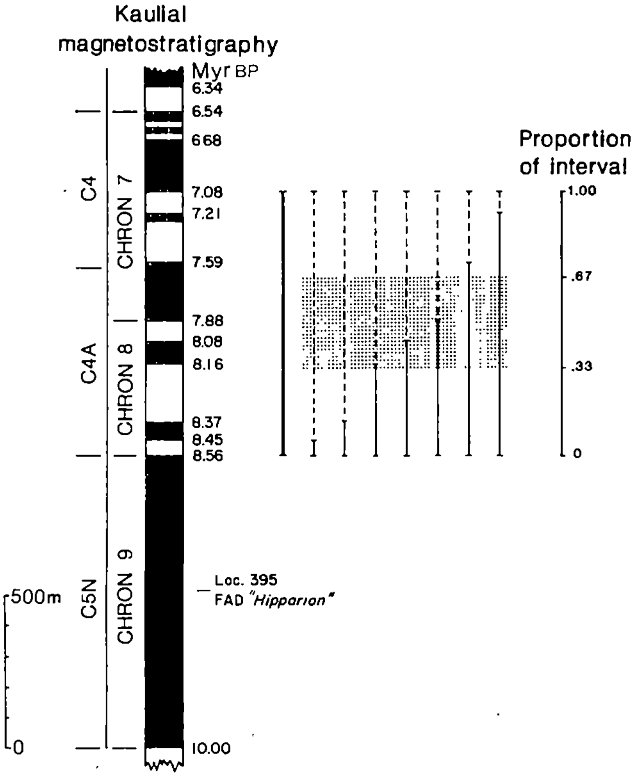

Fig. 2 Magnetostratigraphy from the Kaulial section in the Khaur area[5] illustrating the resampling method discussed. Absolute ages are indicated from the geomagnetic reversal timescale whenever a polarity interval is represented by at least three palaeomagnetic samples. Two timescales are used: that of Mankinen and Dalrymple[9] (right) and the new chron names (left) of Berggren *et al.*[8] given in the text. The first appearance datum (FAD) of "*Hipparion*" occurs within the long normal interval of Chron C5N. On the right, an interval is extracted from the left-hand record that is of about the same duration as Chron C5N. This long interval can be subdivided in seven different ways into complementary segment pairs of known thickness and time span; there result 14 calculations of proportion of sediment thickness and of time span. Of these segment pairs, three divide the long interval into segments between 33 and 67% (stippled band) of the whole. Ten intervals of durations between 1.2 and 1.8 Myr were located in Chrons C4 and C4A; the 104 segment pairs that can be formed within them provide the data in Fig. 3.

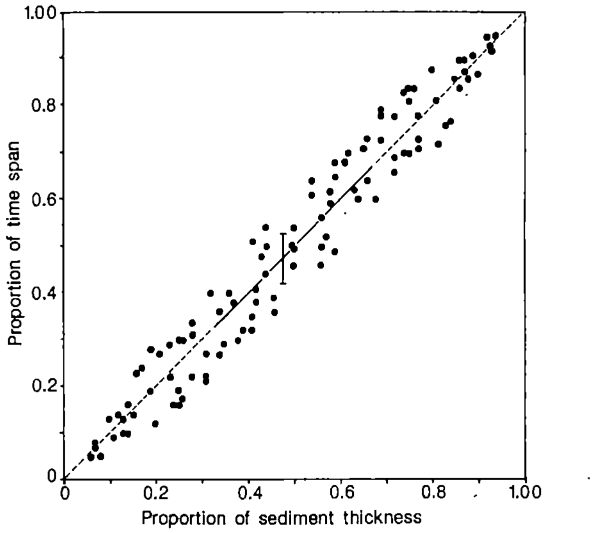

Fig. 3 Variability in proportion of time span in relation to proportion of sediment thickness from subsamples of 10 long intervals in the Kaulial palaeomagnetic section (Fig. 2). Five intervals are longer than the interval of interpolation (1.44 Myr) and five are shorter. Each subsample of a long interval gives rise to two complementary data points whose proportions along either axis sum to 100%. For this reason, the graph is unchanged by a 180° rotation about its centre. The standard error (vertical bar) of 0.06 (6%) was calculated for data in the region of the solid line ($n=40$), corresponding to subsamples of 50±17% of the whole interval. The value of ±6% appears characteristic of a considerably wider range of sediment proportions, perhaps 18–82%.

The data for demonstrating our approach are contained in two magnetostratigraphic studies of Siwalik sediments from Pakistan[5,6]. Siwalik rocks are a Neogene molassic sequence representing multiple fluvial systems on the southern margin of the Himalayas[7]. The pattern of Siwalik sediment accumulation through the middle to late Miocene in northern Pakistan is illustrated in Fig. 1. The Khaur sections exhibit higher sediment accumulation rates because they were closer than the Chinji sections to the inferred source area. In both areas, a change in sediment accumulation rate occurred between 10 and 11 Myr in response to an episode of Himalayan uplift[6]. This event, the major secular trend, constitutes a change in the controls of the sedimentation system. In each geographical location, sediment accumulation appears stationary on either side of this event. For the remainder of the discussion, we focus on a portion of the Khaur data.

Magnetostratigraphic data from the Khaur area are documented in 14 measured stratigraphic sections[5], each spanning part of a 2,100-m interval over a lateral extent of ~25 km. (Only two of these sections are shown in Fig. 1.) The sections are correlated by lithological marker horizons and magnetic polarity stratigraphy; sampling densities ranged from 1 in 3 m to 1 in 23 m. Altogether, the composite Khaur section represents 6.5–10.0 Myr, Chrons C4–C5N (terminology of Berggren *et al.*[8]). (We indicate also the GRTS of Mankinen and Dalrymple[9] in Fig. 2, for consistency with earlier studies. The choice of timescale does not affect the results of the technique presented here.) The longest continuous magnetostratigraphic section in deposits younger than 11 Myr, from Kaulial Kas (a local valley name), serves as the basis for the example discussed below (Fig. 2). The sampling density for this section ranged from 1 in 19 m to 1 in 23 m.

Siwalik sediments, rich in mammalian fossil remains, constitute the standard for South Asian, Neogene mammalian biostratigraphy[10,11]. The first appearance of the three-toed horse "*Hipparion*" in the Khaur Siwalik sequence is significant, both because it marks a rapid faunal turnover within the Siwalik mammalian fauna[10] and because it is used to link Miocene mammalian sites in the Old World[12]. "*Hipparion*" includes several hipparionine taxa not always represented by fossils diagnostic to the species level.) Since the first appearance of "*Hipparion*" in the Siwaliks occurs >2 Myr later than its first appearance in European and African sites[12–15], this event is also controversial. But it lies in the middle of the long normal interval of Chron C5N, thus being a genuine problem in age interpolation.

In the Kaulial section, the lowest occurrence of "*Hipparion*" is at the Harvard-Geological Survey of Pakistan Locality 395 (J. Barry, personal communication). Stratigraphically, Locality 395 lies 510 m above the base of the long normal unit, which is 940 m thick in Kaulial Kas (Fig. 2)[5]. A linear interpolation estimates this event to be 0.78 Myr younger than the age at the base of the long normal unit, or 9.22 Myr in absolute time. The "*Hipparion*" datum is near the middle of the long normal unit. To assess the expected error of this age estimate, we must know how the proportion of time span varies in relation to about half the sediment thickness for time intervals about the same length as the long normal period. Within the combined sequence of

Chrons C4-C4A, it is possible to delimit various intervals of durations between 1.2 and 1.8 Myr. These intervals can be subdivided into complementary pairs of segments, some representing about half of the full interval. For each segment, the discrepancy between proportion of time span and proportion of sediment thickness is directly observable. Thus, we use the pattern of sediment accumulation for a younger portion of the sediment regime to estimate the variance in an older part of the regime; the implied assumption of stationarity is justified by the linear pattern of cumulative stratigraphic thickness over the entire Kaulial sequence.

The resampling technique is illustrated in Fig. 2. The long interval shown as an example is 1.48 Myr in duration according to palaeomagnetic correlation. This interval contains nine short polarity intervals, of which the smallest, at 7.21 Myr, was represented by less than three samples. It was grouped with the next interval below it. (The same criterion was used to group together the four short intervals from 6.54 to 6.68 Myr in other samples.) The long interval may thus be broken into two pieces of known age in seven different ways. For each division, we calculated the proportion of total sediment thickness and proportion of total time span represented in each segment. In all, 10 long intervals, ranging from 1.25 to 1.77 Myr, were identified and subdivided in a similar fashion: these produced 104 segments, represented in Fig. 3.

For the "*Hipparion*" problem, the variance we need should correspond to a thickness proportion of ~0.50. We computed the mean sqaure

$$\frac{\Sigma\ (\text{time proportion} - \text{thickness proportion})^2}{n}$$

of time proportion about thickness proportion for thickness proportions between 0.33 and 0.67 (the solid line in Fig. 3). This quantity is equivalent to the variance in time proportion around a regression line on thickness proportion forced to have a slope of 1 and forced, also, to pass through the origin. For $n = 40$, within the central third of the range, the standard error of this discrepancy is 0.06. Thus, the standard error of the age estimate for the "*Hipparion*" datum should be taken as 6% of 1.44 Myr. By this approach, the age of the first appearance of "*Hipparion*" in the Khaur Siwalik sequence is 9.22 ± 0.09 Myr.

This method of generating a standard error is similar to bootstrapping, jackknifing, and other resampling techniques of modern statistical data analysis. One sample is used to generate many others through intensive resampling of the same data set[16,17]. The data of Fig. 3 are not statistically independent, even though that was assumed for the data of the original sample. In these circumstances, the computed value of 0.06 is a point estimate only, having no standard error itself.

The value 0.06 pertains to this particular situation, that is, the proportion of time span represented by 33-67% of sediment thickness for intervals of 1.2-1.8 Myr duration in Chrons C4 and C4A in the Kaulial section. The same standard error would apply to an interpolation problem concerning 55% of a polarity interval of 1.7-Myr duration, but not to 55% of an interval of 0.5-Myr duration. For this second case, it would be necessary to generate another sampling distribution. It is ultimately the pattern of the observed palaeomagnetic data which determines how the resampling technique can be applied. It would not be possible, in our example, to determine a standard error for intervals of 0.08 Myr duration, this being the shortest interval represented.

This standard error is not the only source of uncertainty in an interpolated age. Palaeomagnetic dates bear the limitations in time resolution of the GRTS, and the stratigraphic placement of reversal boundaries is partly a function of sample spacing. These factors contribute additional uncertainty to any palaeomagnetic age estimate (including age interpolations), although the error should not be a systematic one. The standard error calculated by this resampling method can be considered a minimum value attributable to variability in sediment accumulation rate.

Variation in sediment accumulation rates can be attributed to variation in instantaneous sedimentation rates and in completeness of stratigraphic sections. In a complete stratigraphic section with low variability of instantaneous sedimentation rates, linear interpolation provides the best estimate of age. But most stratigraphic sections cannot be considered complete. Even in systems such as lakes or deep ocean basins where deposition is virtually continuous, sediment is reworked by deep currents, turbidite processes, or dissolution. In fluvial systems, such as the Siwaliks, deposition in any one location is markedly discontinuous, even though deposition may occur most of the time somewhere in the system.

In incomplete sections, the results of linear interpolation are most plausible when gaps are relatively short and evenly distributed throughout the sedimentary record. But such convenient models cannot be assumed in general. The distribution of gaps relative to record must be interpreted in part by stratigraphic information from the section(s) under investigation. Fifty meters of laminated silt imply a markedly different distribution of gaps than 50 m of cross-bedded sandstone. When a pattern of sediment accumulation contains long, unevenly distributed discontinuities, linear age interpolation may be very prone to error; and whenever the magnitude of depositional and erosional events varies widely, the record is likely to be dominated by rare events of high magnitude[18].

These considerations argue against the computation of age-estimate errors according to any general stochastic model. In contrast, the resampling technique demonstrated here indicates the root-mean-square amount by which the interpolated age estimate differs from a 'known' value as a result of the variability in sediment accumulation rates specific to the particular sequence within which the interpolation is taking place. In this way, each system is characterized by its own pattern of variation in sediment accumulation rates, reflecting its own external factors, such as source-area uplift, or internal factors, such as local reworking of sediment.

We thank Gerald Smith, Jennifer Kitchell and Beth Dawson for constructive discussions. Karen Klitz drew Figs 1 and 2. This work was supported in part by NSF grant EAR 8305931 to C.B. and NSF grant OCE83-17546 to L.T.

Light quality and oceanic ultraphytoplankters

Hilary E. Glover, Maureen D. Keller & Robert R. L. Guillard

Bigelow Laboratory for Ocean Sciences, McKown Point,
West Boothbay Harbor, Maine 04575, USA

Photosynthetic prokaryotic picoplankters (<2 μm), *Synechococcus* spp.[1,2], provide a significant fraction of oceanic primary production[3,4]. The significance of similarly sized eukaryotic algae has not been fully appreciated until recently, as they are difficult to isolate in culture and many become distorted or disintegrate in preservatives[5,6]. Yet these eukaryotes, in the size range of *Synechococcus*, to perhaps 10 μm (refs 7–10), often numerically dominate ultraphytoplankton (<10 μm) at deep chlorophyll maxima[5,6,11–13]. Because temporal variability in oceanic productivity seems to be caused by changes at the bottom of the euphotic layer[14], the composition and activity of communities at chlorophyll maxima are of interest. Here we present evidence that eukaryotic ultraplankters have greater photosynthetic and growth efficiencies than *Synechococcus* in the dim blue–violet light occurring at the bottom of the euphotic zone. Our experiments at least partially explain the large numbers of eukaryotic ultraplankters in the open ocean at the 0.5% light level, below the population peak of *Synechococcus spp.*

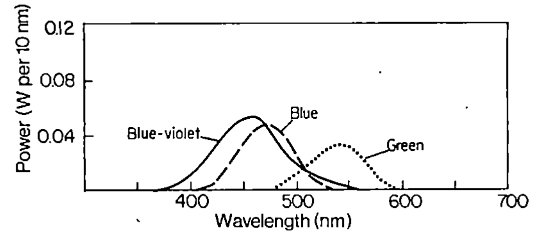

Fig. 1 Spectral quality of plastic filters used in physiological experiments: blue-violet filter (——), maximum transmittance 455 nm; blue filter (- - -), maximum transmittance 470 nm; green filter (· · · ·), maximum transmittance 542 nm.

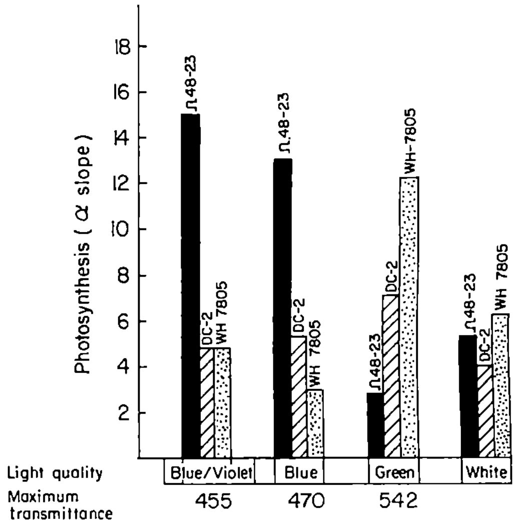

Fig. 2 Photosynthetic efficiencies in different light qualities for an ultraplanktonic prasinophyte clone Ω48-23 (■), *Synechococcus* clone DC-2 (▨) and *Synechococcus* clone WH 7805 (▩). Batch cultures were grown at 20 °C, in 14/10 h light/dark cycles in blue-violet light at 1.6×10^{15} quanta $cm^{-2}\,s^{-1}$. In 'log-phase', we determined chlorophyll *a* concentrations[24] and photosynthetic rates[25] at four rate-limiting fluxes of blue-violet, blue, green or white light, and determined the α slope as a measure of phytosynthetic efficiency[22]. α slope = photosynthesis (mg carbon per mg chlorophyll *a* per h)/irradiance (quanta $\times10^{-16}$ $cm^{-2}\,s^{-1}$).

We compared the performances in culture of oceanic clones of *Synechococcus* and eukaryotic algae from different classes in conditions of nutrient abundance but variable light intensity and quality. We also compared attenuation spectra and fluorescence emission spectra.

All eukaryotic phytoplankters have chlorophyll *a* as their major light-harvesting pigment. Large eukaryotic diatoms and dinoflagellates, which numerically dominate shallow neritic chlorophyll maxima, contain carotenoid pigments (fucoxanthin and peridinin, respectively), which absorb the available green light[15]. In contrast, eukaryotic ultraplankton species do not contain these carotenoids but have chlorophyll *b* or *c* as major accessory pigments[16]. While oceanic *Synechococcus* spp. contains chlorophyll *a*, phycoerythrin is the major light-harvesting pigment[17–20].

Excitation of *Synechococcus* clones with green (530 nm) light produced a much larger fluorescence emission than with blue (470 nm) light. Conversely, ultraplanktonic eukaryotic clones exhibited greater fluorescence emission with blue (470 nm) light than with green (530 nm) light. The ratio of fluorescence emission produced by excitation at 530 nm (green) to that produced by excitation at 470 nm (blue) was calculated for each clone. Except for large diatoms and dinoflagellates, ratios did not exceed 0.7 for eukaryotic algae (0.3–0.4 for ultraplanktonic prasinophytes, 0.4–0.7 for prymnesiophytes and chrysophytes). Highest ratios, 5.2 and 5.4, respectively, were observed for *Synechococcus* clones WH 8018 and WH 7805. These clones contain only phycoerythrobilin (PEB) chromophores in their phycoerythrin[18]. *Synechococcus* clones DC-2 and Syn-48 contain phycourobilin (PUB) in addition to PEB chromophores[18], which shift the excitation wavelength from 530 nm to 510 nm; for these two clones, ratios of fluorescence emission were 2.6 and 2.5 (at 510:470 nm excitation).

We performed photosynthesis and growth experiments in conditions of nutrient abundance but variable light intensity and quality. 'Daylite' fluorescent bulbs in conjunction with coloured filters (Fig. 1) were used to simulate two types of oceanic water[21]—blue-violet (maximum transmittance 455 nm) and blue (maximum transmittance 470 nm)—and coastal water[21]—green (maximum transmittance 542 nm). 'Vitalite' fluorescent bulbs were used to simulate daylight (white light). Photosynthetic efficiences were determined as light-limited α slopes[22] in white, green, blue and blue-violet light. All eukaryotic ultraplankton clones used blue-violet light most efficiently for photosynthesis, while phycoerythrin-rich *Synechococcus* clones photosynthesized most efficiently in green light. An example of this is shown in Fig. 2. *Synechococcus* clone DC-2, containing PUB chromophores, was able to use low fluxes of blue light more efficiently for photosynthesis than could *Synechococcus* clone WH 7805, which lacks PUB chromophores. Extending these studies to include growth experiments, we found that eukaryotic ultraplankton clones grew fastest in low fluxes of blue-violet light. In contrast, *Synechococcus* clones grew best in green light (see, for example, Fig. 3).

Even though larger eukaryotic algal clones could effectively use blue-violet light, they could not utilize very low photon flux densities as efficiently as could eukaryotic ultraplankters. This may be partly due to a more efficient absorption of light with decreasing cell size[23]. Thus, the bottom of the euphotic zone in the open ocean may provide insufficient photon flux densities for efficient photosynthesis and growth of larger forms.

Our experiments suggest that *Synechococcus* clones containing PUB chromophores should out-compete other *Synechococcus* clones at depth. Moreover, oceanic eukaryotic ultraplankters should have a competitive advantage over *Synechococcus* at the base of the euphotic zone in dim blue-violet light because of

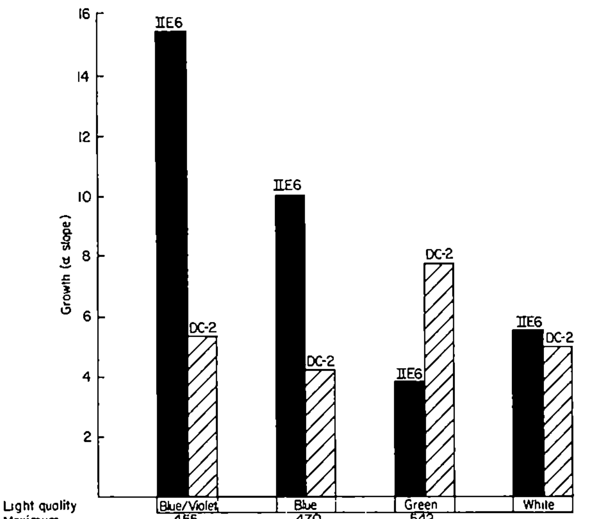

Fig. 3 Growth efficiencies in different light qualities for ultraplanktonic prymnesiophyte clone II E6 (■) and *Synechococcus* clone DC-2 (▨). We determined the daily increase in fluorescence[26] and cell numbers in batch cultures at 20 °C, in 14/10 h light/dark cycles at four rate-limiting fluxes of blue-violet, blue, green and white light, and determined the α slope as a measure of growth efficiency. The α slope = specific growth rate (h^{-1})/irradiance $(\text{quanta} \times 10^{-16}\ \text{cm}^{-2}\ \text{s}^{-1})$.

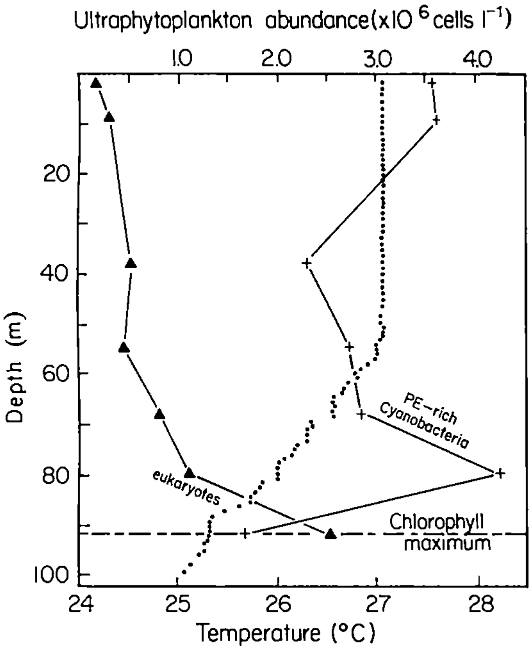

Fig. 4 Depth profiles of phycoerythrin(PE)-rich *Synechococcus* (+), eukaryotic ultraplankters (▲) and temperature (●). Data were collected from the Sargasso Sea at 34°49′ N, 66°20.6′ W in August 1983. Pump water was immediately filtered at <125 mm Hg through a 3-μm Nuclepore filter. The filtrate was passed through a 0.2-μm Nuclepore filter and cells were classified as either *Synechococcus* or eukaryotes[6].

functional differences in their pigment compositions. Recent field experiments support this hypothesis[20]. Ultraplankters sink at negligible rates[12], thus biomass peaks below the surface mixed layer[6,13] in the open ocean may be attributed to *in situ* growth. One advantage of inhabiting this dimly illuminated environment is the proximity to richer nutrient levels from upward advection across the thermocline. This enrichment enables cells to synthesize additional pigments for photoadaptation. Below the upper isothermal layer in the Sargasso Sea (Fig. 4), we found the maximum numbers of *Synechococcus* occurring at about 1% of surface irradiance, while the maximum abundance of eukaryotic ultraplankters occurred below this, constituting a chlorophyll maximum. This agrees with previous data from the central gyre of the North Atlantic[6].

It should also be noted that photosynthetic studies in deck-incubators, under natural light modulated in intensity but not quality, will underestimate the contribution of eukaryotic ultraplankters to the *in situ* rate of oceanic primary production.

We thank E. M. Haugen, A. E. Smith and R. Spinard for assistance with this research and C. S. Yentsch and L. A. Codispoti for reviewing this manuscript. The work was supported by NSF grants OCE-84-05299 and OCE-82-08626. This is Bigelow contribution 84034.

Birds that 'cry wolf'

Charles A. Munn

Wildlife Conservation International, New York Zoological Society,
The Bronx Zoo, Bronx, New York 10460, USA

Reports of animals using alarm calls deceptively are rare (refs 1–3 and R. Cheney and D. Seyfarth, personal communication in ref. 4). Here I have studied two species of flycatching birds in Amazonia, *Lanio versicolor* and *Thamnomanes schistogynus*, which lead flocks of mixed species in the canopy and understorey of the forest, respectively, and act as sentinels, giving alarm calls at the approach of bird-eating hawks. These two species feed to a large extent on the insects flushed out by the foraging of the rest of the flock. My observations suggest that *L. versicolor* and *T. schistogynus* use the predator alarm call deceptively to distract other birds, thereby increasing their own chances of capturing arthropods. This result suggests that deception among animals may be more widespread than is generally assumed.

The mixed-species bird flocks of the Amazon forest are the most diverse multi-species associations described for any organisms[5–8]. At Cocha Cashu, Manu National Park, south-east Peru (71° 19′ W, 11° 51′ S, elevation ~400 m), the white-winged shrike-tanager (*L. versicolor*, Thraupinae) leads permanent mixed-species flocks in the canopy of the forest and helps maintain flock cohesion by means of loud vocalizations throughout the day[6–8]. At the same site, the bluish-slate antshrike (*T. schistogynus*, Formicariidae) performs the same role in permanent mixed-species flocks in the understorey[5–8].

In addition to their roles as flock leaders, these two species are also flock sentinels, as they are virtually always the first

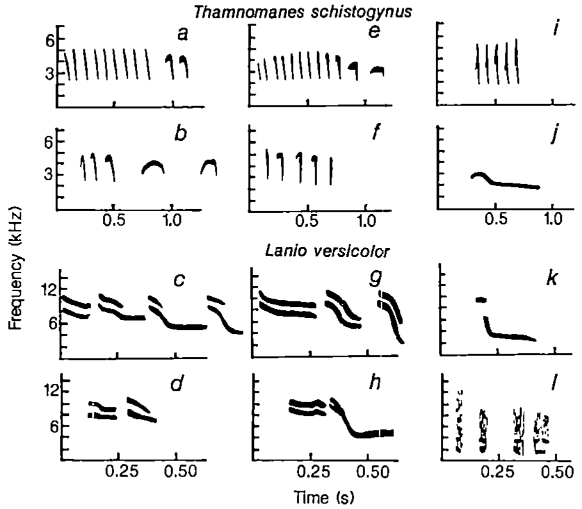

Fig. 1 Tracings of spectrograms of true alarm calls (*a–d*), false alarm calls (*e–h*), and other (non-alarm) calls (*i–l*) of *T. schistogynus* and *L. versicolor.* True alarms are given in response to real danger; false during a chase after arthropods; and other calls in entirely different contexts. The non-alarm rattle (*i*) was used as a control in the experiment. True and false alarms of *T. schistogynus* are characterized by repeated staccato notes of narrower bandwidth than the notes of the non-alarm rattle (*i*), which apparently is given to promote flock cohesion[4-6]. The true and false alarms of *L. versicolor* are characterized by descending notes with simple, strong harmonic structure; both characteristics are not found in other calls. Note that for *L. versicolor*, the timespan is halved, while the frequency range is doubled compared with the results for *T. schistogynus.* Spectrograms were made on a Kay Elemetrics 6061B machine with wide-band filter.

Table 1 Response of other understorey flock species to playback of true and false alarms and rattle (control) of *T. schistogynus*

	Bird reacts	Bird does not react	
Rattle (control) (*i* in Fig. 1)	0	15	
True alarm call (*a* in Fig. 1)	13	0	$P > 0.153$
False alarm call (*e* in Fig. 1)	13	3	
			$P < 0.001$

Other birds are equally startled by the true and false alarms of *T. schistogynus*, while they are not startled by the rattle. Fisher exact tests were used to calculate the probabilities associated with the two comparisons. Recordings and playback were via a Panasonic RQ 356 cassette recorder, JVC shotgun microphone, and a modified Olympus SMW SP5 field speaker.

species to give loud alarm calls at the approach of bird-eating hawks of the genera *Micrastur*, *Accipiter* and *Leucopternis*[5,6,8]; they are also the first to give short alarm calls when harmless hawk-sized birds fly by[6]. Finally, they are also the first species to sound an alarm when hawk models are shot past them[6]. Other species of flock birds look up, freeze, dive or jump into cover when a sentinel sounds the alarm.

The sentinel role has enabled *T. schistogynus* and *L. versicolor* to establish a novel symbiotic relationship with other flock members. Both sentinel species rely on the insect-flushing abilities of other flock species for ≥85% of their food[6]. Rarely do they steal arthropods directly from the bills of other birds. Rather, they sit in the centre or beneath a group of actively foraging flock species and fly out or dive down after dropping arthropods flushed from hiding by the more active species. When a bird of another species begins to chase an arthropod that it has flushed out, the faster-flying, more aerobatic sentinel often catches the arthropod first. It is during these multi-bird aerial tumbles after arthropods that both species of sentinel give the same alarm call used when a hawk attacks or flies by. I interpret these calls as false alarm calls, presumably used by the sentinel to distract other birds and thereby to increase its own chance of capturing the arthropod. These aerial contests are over in less than a second, so even a slight hesitation by other birds increases the likelihood that the sentinel will reach the arthropod first.

Using the following criteria, I classified 106 of 718 alarm calls as true or false: true if simultaneously I saw a hawk-like object fly by or if other flock species subsequently alarmed and froze for several minutes, and false if the sentinel flew into the open after a falling arthropod while I simultaneously had a clear view of the entire region within 20 m of the bird and could thus eliminate the possibility of a passing hawk. Sentinels remained motionless on partially concealed perches when giving true alarms, whereas when giving false alarms, they flew with other birds into the open in pursuit of flushed arthropods. Flying into the open is inappropriate for escape from fast-flying bird hawks. Furthermore, the probability is vanishingly small that hawk-like birds repeatedly flew by at the same instant that sentinels were competing with other birds for falling arthropods, as neither type of incident occurred more than three times per hour.

The context of the false alarms further strengthens my interpretation. *L. versicolor* sounded the alarm significantly less often when it alone was chasing an arthropod than when another bird was involved also (19 instances out of 131 versus 34 out of 56, $\chi^2 = 39.0$, $P < 0.001$). Furthermore, the rate of sounding of alarms increased dramatically when either sentinel species was feeding its young. As most of these additional alarms were given during multi-bird chases after flushed arthropods, and the young were often too far from the adults to hear the calls, I classified most of these additional alarms as false. Thus, the rate of sounding of alarm calls was higher when the opportunity for obtaining more food was greater and when the need for that food was more pressing.

Known true and false alarms are strikingly similar in outline and frequency on spectrograms, whereas both true and false alarms are very different from other calls in the repertoire of the two sentinel species (Fig. 1). Although alarm calls can vary from one or two notes to a whole series of sharp notes, only the first one or two are needed to trigger a startle or escape reaction from individuals of other species.

The postulated effect of the alarm calls, indeed the effect of only hearing the calls, was confirmed by an experiment in which I played back cassette recordings of a non-alarm rattle call, a known true alarm, and a known false alarm of *T. schistogynus* to understorey flock species. The birds treated both the true and the false alarms as true alarms, while they ignored the rattle (control) (Table 1). The canopy flocks foraged too high to permit the same experiment, but observation of natural true and false alarms of *L. versicolor* supported the interpretation of deceptive alarm calls. Even though about half of all *L. versicolor* alarm calls are false (56 out of 104 categorizable alarm calls), canopy flock birds reacted positively to 31 of 41 alarm calls of unknown context, which is significantly greater than the percentage of true alarms (46%; $\chi^2 = 9.14$, $P < 0.01$). On two of these 31 occasions, I saw another bird react to the call as if it were a true alarm call and then saw the *Lanio* fly out after an insect. In the 10 cases in which a bird showed no reaction to a sentinel alarm call, the bird was already in the open and was thus able to scan for hawks without moving. In contrast, birds with their heads inside leaves, or under their wings, bathing, or in other vulnerable positions, typically showed the most dramatic escape responses by diving for cover when any alarm call was given.

Theoretically, as in the story of the boy who cried "Wolf!" (ref. 9), there should be an upper limit to the proportion of false alarms that can be supported by a given rate of occurrence of true alarms. The potential penalty, however, for ignoring even one alarm call might be death; so it is not surprising that flock birds seem to take all alarm calls seriously, whether true or false. Presumably, the cost to the beater species of reacting to false alarms is the occasional loss of an arthropod to the sentinel, while the only cost to the sentinel is the energy used in producing the call. The possible benefit to the sentinel of sounding a false alarm could be a substantial increase in its daily intake of arthropods. Unfortunately, the outcomes of most of the multi-bird scrambles for arthropods were concealed by vegetation, so I cannot compare the rate of prey capture by sentinels when silent with their capture rates when giving false alarms.

In general, an animal competing with others for a resource might use deceptive alarm calls in contests of predictably short duration in which rivals who check for danger automatically lose.

Synapsin I is a microtubule-bundling protein

Anthony J. Baines* & Vann Bennett

Department of Cell Biology and Anatomy,
Johns Hopkins University School of Medicine,
725 North Wolfe Street, Baltimore, Maryland 21205, USA

Synapsin I, a synaptic vesicle protein, is thought to be involved in the regulation of neurotransmission through its phosphorylation by the cyclic AMP-dependent and Ca^{2+}/calmodulin-dependent protein kinases which become activated upon depolarization of nerve endings[1-3]. However, despite its recent characterization[4] as a spectrin-binding protein immunologically related to erythrocyte protein 4.1, other interactions of synapsin I with structural proteins remain unknown. We report here that synapsin I can co-cycle with microtubules through three cycles of warm polymerization and cold depolymerization. Synapsin I binds saturably to microtubules stabilized by taxol, with an estimated dissociation constant (K_d) of 4.5 μM and a stoichiometry of 1.2 mol of synapsin binding sites per mol tubulin dimer. Synapsin I also increases the turbidity of tubulin solutions at 37 °C, but without causing detectable alterations in the critical concentration required for polymerization. Mixtures of synapsin I and tubulin observed by negative stain electron microscopy contain bundles of microtubules, accounting for the effect of synapsin I on tubulin turbidity. Synapsin I is thus a candidate to mediate or regulate the interaction of synaptic vesicles with microtubules.

Synapsin I was prepared from calf brains, as described in Fig. 1, by modifications of our previous procedure[4]. Tubulin was prepared from three-times-cycled microtubule protein from calf brain by chromatography on Whatman DE53 cellulose[5]. In preliminary experiments, synapsin I (0.5–5 μm) co-sedimented with microtubules after incubation with tubulin (10–50 μM, with reference to dimer) at 37 °C for 30 min, in a buffer optimal for microtubule assembly (0.1 M Na-PIPES, 1 mM MgCl$_2$, 1 mM GTP, 1 mM dithiothreitol (DTT), 1 mM EGTA, 1 mM NaN$_3$ *p*H 6.6: PMGDE buffer) (data not shown). However, an interaction between synapsin I and tubulin dimer was not detectable by sedimentation of mixtures of synapsin I and tubulin through linear sucrose gradients at 4 °C, suggesting that synapsin I will interact strongly only with tubulin in polymeric form.

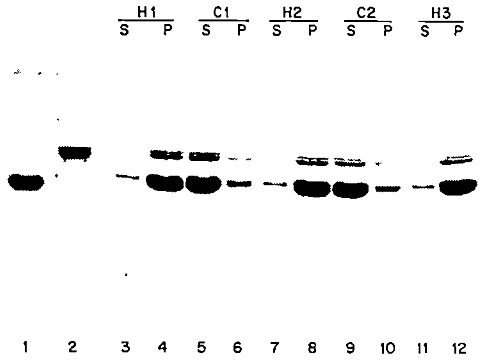

Fig. 1 Synapsin I co-cycles with tubulin during three cycles of warm polymerization and cold depolymerization. Supernatants (S) and pellets (P) from the first, second and third warm centrifugation steps (H1, H2 and H3), as well as those for cold centrifugation (C1 and C2) were analysed on an SDS-polyacrylamide gel. Lane 1, DEAE-purified tubulin (30 μg); 2, synapsin I (15 μg); 3, H1S; 4, H1P; 5, C1S; 6, C1P; 7, H2S; 8, H2P; 9, C2S; 10, C2P; 11, H3S; 12, H3P.

Methods. Synapsin was purified by modifications of our previous procedure[4]. Briefly, synapsin I was extracted from demyelinated brain membranes in the presence of 0.15 M NaCl, 1% Triton X-100 *p*H 7.1, and purified by chromatography on hydroxylapatite and carboxymethyl cellulose (A.J.B. and V.B., manuscript in preparation). Synapsins 1a and b were more than 90% of the protein in the final preparation, with a further 6–8% being proteolytic degradation products of relative molecular mass (M_r) > 50,000 (see lane 2, above). Tubulin was purified from three-times-cycled microtubules by DEAE chromatography[5]. Tubulin was about 98% of the final preparation, the major contaminant being MAP-1, which constituted no more than 1% of the total protein (see gel lane 1, above). For the experiments shown in Figs 2, 3 and 4, the tubulin was completely freed of MAP-1 by centrifugation of microtubules in the presence of 0.5 M NaCl: the microtubule pellet formed under these conditions contains no detectable MAP-1. Tubulin was stored as a microtubule pellet at −80 °C, and was cycled once prior to use. In the cycling experiment shown, synapsin I (7 μM) was combined with tubulin (66 μM) at 0 °C in PMGDE buffer (see text for buffer composition). Glycerol was added to give a final concentration of 20% (v/v) and the mixture was brought to 37 °C for 30 min. The microtubules that formed during the incubation were collected by centrifugation for 25 min at 150,000*g*, and were depolymerized in one-third of the initial volume of ice-cold PMGDE. After incubation for 30 min on ice, with intermittent shearing through a 26-gauge needle, the mixture was clarified by centrifugation at 150,000*g* for 25 min at 0 °C. Glycerol was added to the supernatant after this spin, the mixture brought to 37 °C, and the cycle repeated twice more. Samples were withdrawn from all supernatants and resuspended pellets produced for SDS-polyacrylamide gel electrophoresis. The pellets from C1 and C2 were resuspended in 1% SDS. Concentrations of synapsin I were estimated spectrophotometrically, assuming $E^{1\%}_{1\,\mathrm{cm}} = 6.74$ at 277 nm (ref. 12). Synapsin was assumed to be a monomer of M_r 75,000. Tubulin concentrations were estimated by a dye-binding assay[25] using bovine serum albumin as standard: molar concentrations were calculated assuming a tubulin dimer of M_r 100,000.

One characteristic of many microtubule-associated proteins (MAPs) is that they co-cycle with tubulin during repeated cycles of warm polymerization and cold depolymerization. When mixtures of synapsin I and tubulin were subjected to repeated

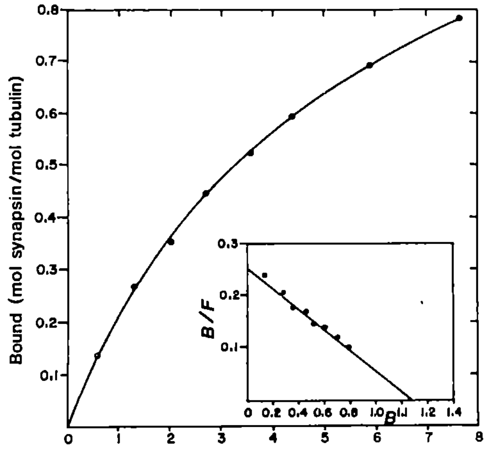

Fig. 2 Binding of ^{125}I-synapsin I to taxol-stabilized microtubules. *a*, Association of various concentrations of ^{125}I-synapsin I with 1.0 μM taxol-tubulin. Binding is expressed as mol synapsin I bound per mol tubulin (dimer), after subtraction of blank values. *b*, Data plotted according to the Scatchard equation, $B/F = N/K - B/K$ (ref. 9), where B is moles of synapsin bound per mole of tubulin (dimer), F is the concentration of unbound synapsin (μM), N is the number of binding sites (mol mol^{-1}) and K is the dissociation constant. The line shown is a calculated best fit for a single class of sites, which yields $K = 5$ μM and $N = 1.2$.
Methods. Synapsin I was labelled with ^{125}I-labelled Bolton Hunter reagent and diluted with unlabelled synapsin I to give 8.76×10^5 c.p.m. nmol^{-1}. DEAE-purified tubulin (52 μM dimer) was polymerized in PMGDE buffer without glycerol, and taxol was added from a 10 mM solution at 37 °C for 20 min. The resulting microtubules were resistant to cold depolymerization, and >98% of the tubulin was pelletable during centrifugation at 100,000*g* for 25 min. In the binding assay, taxol-tubulin was diluted to a final concentration of 1.0 μM (relative to dimer), with various concentrations of ^{125}I-synapsin I in PMGDE buffer, to give a volume of 100 μl, and allowed to stand for 1 h at 23 °C. Samples of 90 μl were layered over 100 μl of 20% sucrose, 20 μM taxol in PMGDE, in Beckman airfuge tubes. Taxol-stabilized microtubules, with bound ^{125}I-synapsin, were pelleted during centrifugation at 100,000*g* for 30 min in the airfuge. Aliquots of 50 μl supernatant were withdrawn from the meniscus, and the remaining supernatant aspirated. Supernatants and pellets were counted for ^{125}I in a γ-counter. Blanks, from which tubulin was omitted, were included in the assay. All points were determined in duplicate, the means of which are shown.

cycles of warm polymerization and cold depolymerization, synapsin I co-cycled with microtubules (Fig. 1). (Synapsin I alone showed no tendency to polymerize in the warm.) The ratio of synapsin I to tubulin in the experiment shown decreased by only 5% during three cycles (as judged by elution of dye from Coomassie blue-stained SDS-polyacrylamide gels of the pellets, followed by reading absorbance at 605 nm)[6], and we conclude that co-cycling reflects a stable interaction between tubulin polymer and synapsin I.

To quantitate such an interaction, the association of ^{125}I-synapsin with taxol-stabilized microtubules was measured. Taxol is an antimitotic drug[7] which virtually eliminates the critical concentration required for tubulin polymerization[8], allowing the use of very dilute tubulin polymers for saturation binding analysis. Binding of 0–7.5 μM ^{125}I-synapsin was examined at both 1.0 μM (Fig. 2) and 1.2 μM (not shown) tubulin (concentrations being expressed relative to dimer). When the data were plotted according to the Scatchard equation[9], a single class of binding sites (1.2 mol binding sites per mol tubulin dimer) was revealed, with a K_d of 4.5 μM. Experimental limitations on the concentration of synapsin prevented more than about 60% saturation of tubulin; thus additional lower-affinity classes of binding sites or negative cooperativity may become apparent at higher concentrations of synapsin (4.5 μM may be a minimum estimate for the K_d as drug-treated tubulin may not be as active as native tubulin). Synapsin I may also undergo limited self-association in the assay conditions used (see below), which may affect the apparent stoichiometry of the reaction.

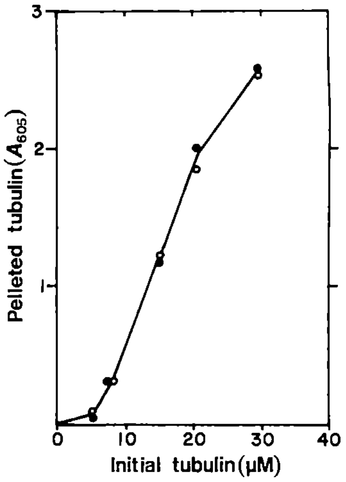

Fig. 3 Synapsin I does not alter the critical concentration for polymerization of tubulin. Various concentrations of tubulin (4.9–29.4 μM) were incubated with (●) or without (○) 5 μM synapsin I in PMGDE buffer containing 5% glycerol. After 30 min at 37 °C, the mixtures were centrifuged for 25 min at 100,000*g*, and samples of supernatants and pellets analysed by gel electrophoresis: tubulin was quantitated by dye elution from Coomassie-stained gels[6]. Data are plotted as total tubulin (μM) against tubulin pelleted (expressed as A_{605} of dye eluted from stained gels). The critical concentration is assumed to be represented by the point at which the linear portion of the curve intercepts with the *x*-axis. A critical concentration of 4–5 μM tubulin is estimated in the presence and absence of synapsin I.

Synapsin I increases the turbidity of tubulin solutions when incubated at 37 °C (not shown). Microtubule-associated proteins also do this, seemingly by reducing the critical concentration required for polymerization (see for instance refs 10, 11). That synapsin I might act similarly was examined in Fig. 3. Various concentrations of tubulin were incubated in PMGDE buffer containing 5% glycerol, in the presence or absence of 5 μM synapsin I. After 30 min at 37 °C, microtubules were collected by centrifugation. Pelleted tubulin was separated from bound synapsin by electrophoresis on SDS-polyacrylamide gels, and quantitated by dye elution from Coomassie blue-stained gels[6]. Synapsin I had no detectable effect on the final extent of tubulin polymerization, and a critical concentration of 4–5 μM is estimated both in the presence and absence of synapsin I (Fig. 3). By contrast, the addition of MAP-2 to tubulin in our assay conditions greatly reduces the critical concentration.

Since the increase in turbidity of tubulin solutions could not be accounted for by lowering of the critical concentration, synapsin I/tubulin mixtures were examined by negative stain electron microscopy (Fig. 4). While control tubulin formed single microtubules of normal appearance, randomly arranged on electron microscope grids, mixtures of synapsin I and tubulin revealed bundles of microtubules in tightly packed arrays. The extent of bundling was dependent on the amounts of synapsin I and tubulin in the incubation mixtures: at high concentrations of synapsin I and tubulin (for example 5 μM and 25 μM respectively), the bundles were sufficiently large to be easily distinguished in the light microscope.

Cross-linking of microtubules by synapsin implies that either synapsin has two or more binding sites for microtubules, or that synapsin has one tubulin binding site and achieves cross-linking by self-association. Synapsin is monomeric in dilute solution[4,12]; however, in concentrated solutions of synapsin (1.5 mg ml^{-1}),

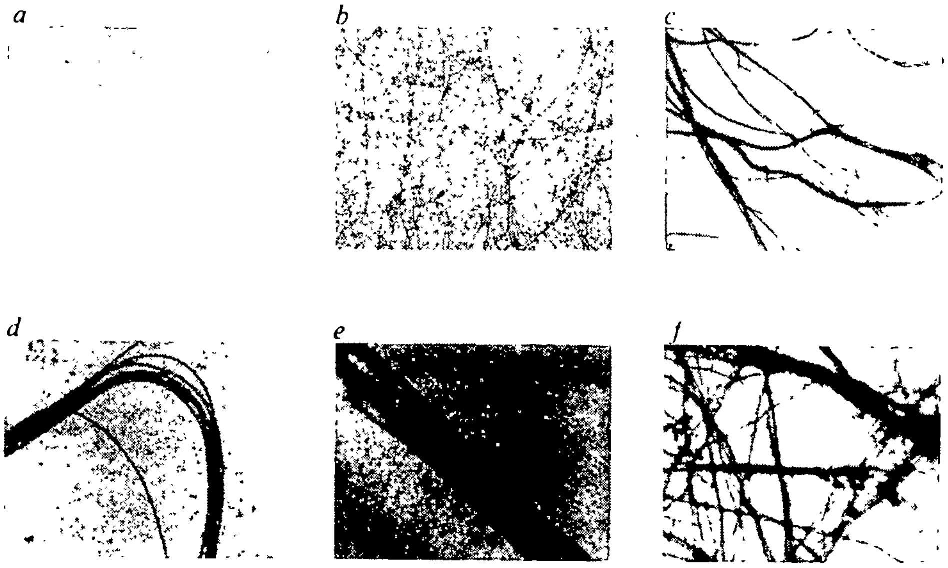

Fig. 4 Electron microscopy of synapsin I, tubulin and synapsin I/tubulin mixtures. Synapsin I (5 μM) and tubulin (10 μM or 25 μM) were incubated separately or together at 37 °C in PMGDE buffer in the absence of glycerol. After 30 min, samples were applied to Formvar carbon films on 400-mesh grids. The samples were rinsed with buffer, stained with 1% unbuffered uranyl acetate and examined in the electron microscope. *a*, Synapsin I alone; *b*, tubulin (10 μM) alone; *c*, *d*, *e*, synapsin I plus tubulin (10 μM); *f*, synapsin I plus tubulin (25 μM). The scale bar (lower right) represents 4.7 μm in *a*, *b*, *c* and *f*, 1.2 μm in *d* and 0.6 μm in *e*.

oligomers of synapsin up to tetramer in size are revealed by HPLC gel filtration or by chemical cross-linking (A.J.B. and V.B., unpublished data, but see also ref. 12). Therefore, it is possible that bundling of microtubules is dependent on self-association of synapsin into multivalent complexes. In future work it will be important to investigate the factors that regulate self-association, and the self-association state of synapsin in its vesicle-bound form.

In spite of repeated reports, based on electron microscopy, that synaptic vesicles might be attached to microtubules[13-16], the cytoskeletal interactions of synaptic vesicles are still very unclear (compare refs 14 and 17 but see also ref. 18). However, interactions between secretory vesicles and microtubules have been detected in reconstitution experiments[19,20] and, more recently, in taxol-stabilized complexes of microtubules and secretory granules isolated from exocrine pancreas[21]. Our observations suggest that synapsin I might act to link or regulate the linkage of microtubules to synaptic vesicles. The role of such a linkage is open to speculation, but it might play a part in axonal transport of vesicles, or in the placement of synaptic vesicles in the presynaptic active zones. The association of synaptic vesicles with microtubules is likely to be transient *in vivo*, as it is known that the interaction of synapsin I with its membrane binding site is weakened upon phosphorylation by Ca^{2+}/calmodulin-dependent protein kinase[2]. Furthermore, in view of alterations in the activities of MAP-2[22,23] and tau[24] in response to their phosphorylation, it is possible that the tubulin binding activity of synapsin will be altered by its phosphorylation. It is not yet known how the spectrin-binding activity of synapsin I relates to its tubulin-binding activity.

Functional corticotropin releasing factor receptors in the primate peripheral sympathetic nervous system

Robert Udelsman*, James P. Harwood, Monica A. Millan, George P. Chrousos†, David S. Goldstein‡, Reuven Zimlichman‡, Kevin J. Catt & Greti Aguilera

Endocrinology and Reproduction Research Branch, NICHD; * Surgery Branch, NCI; † Developmental Endocrinology Branch, NICHD; and ‡Hypertension-Endocrine Branch, NHLBI, National Institutes of Health, Bethesda, Maryland 20892, USA

Corticotropin releasing factor (CRF) is a key hormone in the integrated response to stress, acting both as the major regulator of pituitary adrenocorticotropic hormone (ACTH) release and as a neuropeptide in the brain[1,2]. The actions of CRF are mediated by specific plasma membrane receptors in the anterior pituitary gland[3] and in discrete brain areas including the cerebral cortex and several regions related to the limbic system[4,5]. In addition to the pituitary and central actions of CRF, systemic administration of the peptide in the rat[6], dog[7,8], monkey[9] and man[10-12] causes hypotension and tachycardia because of a decrease in peripheral vascular resistance. These observations, in conjunction with the finding of immunoreactive[13-17] and bioactive[14,18] CRF in peripheral tissues, suggest that the peptide is locally released in tissues to act as a neurotransmitter or paracrine hormone. As CRF is present in the adrenal medulla[13,14] and the peptide is known to modulate

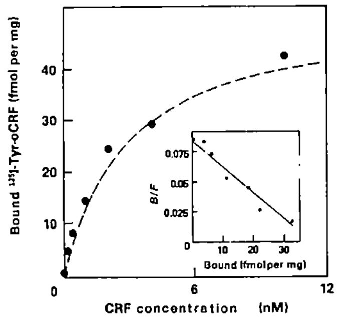

Fig. 1 Saturation curve and Scatchard analysis (inset) of ^{125}I-Tyr-ovine CRF binding to adrenal medulla membrane particles in the rhesus monkey. Each point represents the mean of duplicate incubations from a representative experiment.

Methods. Tissue was minced and homogenized in a 50 mM-Tris-HCl buffer (*p*H 7.4) containing 5 mM $MgCl_2$ and 2 mM EGTA, by six strokes on a mechanical homogenizer (Techmar). Homogenates were filtered through nylon gauze and centrifuged at 30,000*g* for 30 min at 5 °C. The membrane-rich pellet was resuspended in the same buffer to give a protein concentration of 2-8 mg ml^{-1}. Aliquots of 100 μl of membrane suspension were incubated with 100,000 c.p.m. of ^{125}I-Tyr-ovine CRF (0.1 nM) in a total volume of 300 μl of 50 mM Tris-HCl buffer containing 5 mM $MgCl_2$, 2 mM EGTA, 0.1% bovine serum albumin (BSA) and 100 kIU ml^{-1} of aprotinin (Sigma). After incubation for 30 min at 22 °C, bound radioactivity was separated from free tracer by centrifugation at 1,000*g* for 3 min at 4 °C following addition of 7.5% polyethylene glycol (PEG) in 50 mM Tris-HCl, *p*H 7.4. The precipitate was washed again with PEG, and the tips of the tubes were removed and analysed for radioactivity in a Beckman γ-spectrometer. Tracer degradation after 60 min incubation was <10% as evaluated by rebinding to rat pituitary membranes. Receptor concentration and affinity were estimated by computer analysis of the binding data[35], and protein concentration was measured[36] with BSA as a standard.

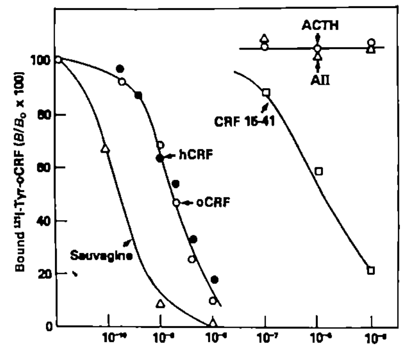

Fig. 2 Ligand specificity of medullary CRF sites in the rhesus monkey. Each point is the mean of duplicate incubations in a representative experiment, performed by the addition of increasing concentrations of CRF and other peptides to adrenal medulla particles incubated with ^{125}I-Tyr-ovine CRF.

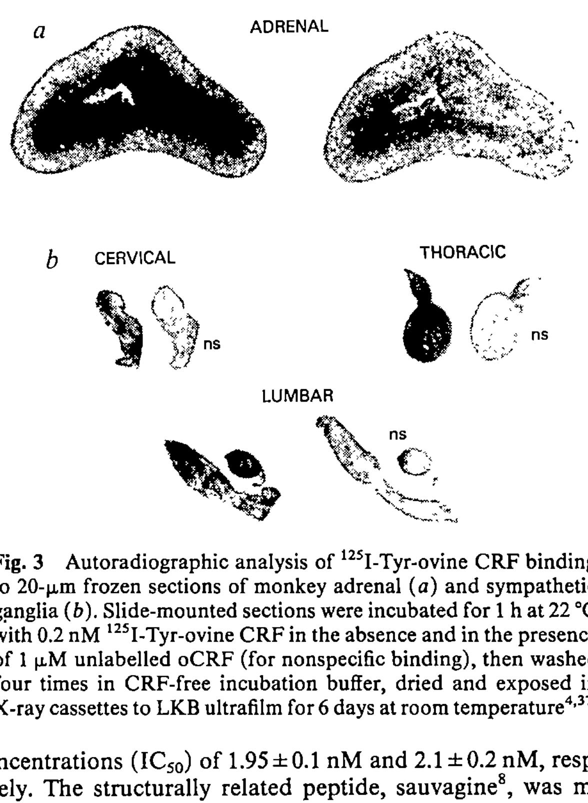

Fig. 3 Autoradiographic analysis of ^{125}I-Tyr-ovine CRF binding to 20-μm frozen sections of monkey adrenal (*a*) and sympathetic ganglia (*b*). Slide-mounted sections were incubated for 1 h at 22 °C with 0.2 nM ^{125}I-Tyr-ovine CRF in the absence and in the presence of 1 μM unlabelled oCRF (for nonspecific binding), then washed four times in CRF-free incubation buffer, dried and exposed in X-ray cassettes to LKB ultrafilm for 6 days at room temperature[4,37].

the central activity of the autonomic nervous system[1], we investigated the possibility that CRF is involved in the regulation of the peripheral autonomic nervous system. Such an action of CRF is supported by our demonstration of specific CRF receptors in the monkey adrenal medulla and sympathetic ganglia. In the adrenal medulla, these receptors are coupled to adenylate cyclase and can stimulate the secretion of catecholamines and Met-enkephalin.

Adrenal glands and lumbar, coeliac, thoracic and cervical sympathetic ganglia were obtained from cynomolgus and rhesus monkeys within 5 min of killing them with an overdose of pentobarbital. The adrenals were cleaned of connective tissue and dissected into three zones; medulla, zona glomerulosa and the inner zones of the cortex. CRF receptors were measured by binding of ^{125}I-Tyr-ovine CRF to the 30,000*g* membrane-rich fractions of tissue homogenates as described previously[3]. No CRF binding was found in either zona glomerulosa or inner zones of the cortex, but saturable, high-affinity binding was present in the adrenal medulla (Fig. 1). Specific binding of CRF in the adrenal medulla was linear up to 800 μg of membrane protein and reached equilibrium between 30 and 60 min at 22 °C with a half-maximum association time of 16 min. Addition of unlabelled oCRF at equilibrium resulted in rapid dissociation of the bound radioactivity with a half-time of 25 min. Scatchard analysis of the binding data revealed a single class of receptors with dissociation constant (K_d) of 5×10^{-9} and 2.3×10^{-9} M in cynomolgus and rhesus monkeys, respectively. The mean value of three experiments including both species was $3.2\pm1.0\times10^{-9}$ M. The binding capacity was also similar in both species, with values of 47 fmol mg^{-1} for cynomolgus and 39.2 ± 4.2 fmol mg^{-1} for the rhesus. This binding capacity of the adrenal medulla membrane fraction was similar to that observed in rat brain[4] and much less than that found in the rat pituitary gland[2].

The ligand specificity of the medullary binding sites for ^{125}I-Tyr-oCRF is shown in Fig. 2. The native peptides oCRF and human CRF were equipotent, with half-maximum inhibitory concentrations (IC_{50}) of 1.95 ± 0.1 nM and 2.1 ± 0.2 nM, respectively. The structurally related peptide, sauvagine[8], was more potent than CRF, whereas the CRF(15-41) fragment was 1,000 times less potent with an IC_{50} of 1.1 μM. The structurally unrelated peptides, ACTH and angiotensin II, showed no binding-inhibition activity at concentrations up to 10^{-5} M. This specificity is similar to that described for CRF receptors in the anterior pituitary gland[3] and in the brain[4]. Similarly, the relative affinities of CRF-related peptides to the adrenal receptor are consistent with the potencies of these peptides to stimulate ACTH release *in vivo*[1,19] and *in vitro*[20,21], and to decrease blood pressure following intravenous administration[6-9].

Binding sites for ^{125}I-Tyr-oCRF in the adrenal medulla were also evident on autoradiographic analysis of the binding in slide-mounted frozen sections of rhesus monkey adrenal glands. Consistent with the results in adrenal membranes, CRF receptors were confined to the adrenal medulla, with no specific autoradiographic staining in the adrenal cortex (Fig. 3*a*). Autoradiographic analysis also demonstrated specific CRF binding in several sympathetic ganglia including lumbar, thoracic, cervical (Fig. 3*b*), and coeliac (not shown). Analysis of the autoradiograms by computerized densitometry indicate optical densities of 0.69 ± 0.05 and 0.23 ± 0.03, respectively, in the

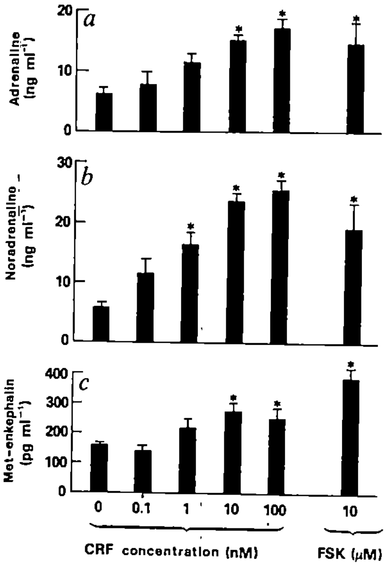

Fig. 4 Adrenaline, noradrenaline and Met-enkephalin production by bovine chromaffin cells during 24 h incubation with corticotropin releasing factor (CRF) or forskolin (FSK). Each bar indicates the mean±s.e. from triplicate incubations. Asterisks indicate significant differences ($P<.05$) as determined by Duncan's multiple range test[38].

Methods. Chromaffin cells were isolated from bovine adrenal glands after retrograde adrenal vein perfusion and collagenase treatment[39] and cultured in 24-well plates (Falcon) containing 1.5 ml per well of basal Eagle's medium with Earle's salts and 25 mM HEPES buffer (Gibco), 5% heat inactivated fetal calf serum, glutamine, penicillin and streptomycin. After incubation for 3 days at 37 °C the media was replaced and either CRF or FSK was added. After an additional 24 h incubation in the presence of CRF or FSK the media were acidified with 150 μl of 1 N HCl and frozen for subsequent assays. Catecholamine levels were determined by HPLC with electrochemical detection[40]. Met-enkephalin levels were determined by radioimmunoassay[41] after ODS-silica column extraction (ImmunoNuclear Corp.).

absence or presence of excess unlabelled CRF. In all sympathetic ganglia, complete inhibition of the specific binding was observed with 10 nM CRF, indicating the high affinity of the binding sites.

As the actions of CRF in well-recognized target tissues such as the pituitary[1,21] and brain[4] are accompanied by stimulation of adenylate cyclase, we determined whether CRF binding sites are associated with a similar function in the adrenal medulla by examining the ability of the peptide to stimulate the conversion of ^{32}P-ATP to cyclic AMP[21]. CRF caused a small but significant and dose-dependent stimulation of adenylate cyclase activity in the adrenal medulla. In three experiments, incubation of membrane-rich particles with ovine CRF increased the enzyme activity by 31±5%, from a basal value of 35.2±1.8 pmol mg^{-1} min^{-1} to a maximum of 46.2±3.2 pmol mg^{-1} min^{-1}, with an ED_{50} of $7.2\pm1.9\times10^{-8}$ M CRF. Stimulation of denylate cyclase was consistently observed with nanomolar oncentrations of CRF, although the ED_{50} for enzyme activation vas higher than the CRF receptor affinity, as frequently observed n broken cell preparations[4,21-24]. The relatively small degree of timulation over basal probably reflects the multiplicity of cell ypes in the adrenal medulla, of which only a small proportion ontain CRF receptors.

To determine whether activation of adrenal medullary CRF eceptors causes changes in secretory activity, the effect of CRF n catecholamine release was analysed in cultured bovine hromaffin cells. During short-term incubation (10–30 min), RF had no effect on catecholamine secretion, whereas nicotine aused a 30-fold stimulation over the basal value for both drenaline and noradrenaline. However, after culture of the hromaffin cells in the presence of CRF for 24 h there was a ignificant increase ($P<0.05$) in catecholamine release, to a maximum of threefold of the basal values for adrenaline (Fig. 4*a*) and fourfold for noradrenaline (Fig. 4*b*) with 10 mM CRF. A further increase in catecholamine release was observed at longer times of culture with 10 nM CRF (eightfold at 48 h and tenfold at 72 h), whereas nicotine-stimulated values remained at a plateau (5-fold). After incubation with nicotine for 72 h, the level of adrenaline increased from 5±1 to 25±1 ng ml^{-1} and that of noradrenaline from 7.1 to 37±3 ng ml^{-1}. A much greater stimulation to 52±1 ng ml^{-1} adrenaline and 69±1 ng ml^{-1} for noradrenaline was observed after incubation with CRF for the same period. The concentrations of CRF required to stimulate catecholamine release were consistent with the K_d of the CRF receptor in the monkey adrenal medulla.

Several peptide hormones have been associated with the function of the adrenal medulla. Vasoactive intestinal peptide (VIP), somatostatin, and many of the proopiomelanocortin derivatives including enkephalin, β-endorphin, ACTH and α-MSH have been identified by radioimmunoassay in normal adrenal medulla and pheochromocytomas[15,25-28]. Several of these peptides are concomitantly released with catecholamines during stimulation of chromaffin cells with carbachol, nicotine or high potassium, suggesting that they are also involved in the stress response[25-27]. Studies with cultured bovine chromaffin cells have shown stimulation of VIP and Met-enkephalin synthesis and release, and an increase in proenkephalin messenger RNA in cultures exposed to high levels of cyclic AMP or forskolin[30,31].

The ability of CRF to stimulate adenylate cyclase activity in the adrenal medulla suggested that the peptide could also modulate the secretion of enkephalin in chromaffin cells. As shown in Fig. 4*c*, addition of CRF to cultured bovine chromaffin cells for 24 h caused a significant increase in Met-enkephalin release, to a maximum of twice the basal value ($P<0.05$) with 10 nM CRF. Forskolin, a known stimulator of adenylate cyclase[32], also enhanced Met-enkephalin and catecholamine release.

The properties of the binding sites for CRF in the adrenal medulla, with specificity for CRF-related peptides, high affinity and the ability to stimulate adenylate cyclase and the secretion of catecholamines and Met-enkephalin, indicate that they represent functional receptors through which CRF modulates adrenal medullary function. The presence of similar binding sites in sympathetic ganglia suggests that CRF is also involved in the extra-adrenal peripheral autonomic nervous system. Both CRF and its receptors are present in the central nervous system at sites where the peptide is known to modify the activity of the autonomic nervous system. The CRF that is present in normal adrenal medulla and pheochromocytomas[13-15] could be locally released to serve as a paracrine or autocrine regulator of the secretion of other stress hormones. Such cyclic AMP-mediated effects of CRF could be particularly relevant during prolonged activation of the medulla, as suggested by the latency of the effect of CRF on catecholamine release, and may be important in long-term adaptation to stress.

A still unresolved question is the functional interaction between the adrenal medulla and cortex. As the circulation within the adrenal gland appears to flow from the cortex to the medulla[33,34], it is difficult to propose a mechanism by which peptides and/or catecholamines released from the medulla could have a direct effect in the cortical zones. However, it is possible that secretory products of the medulla can reach the cortex via local circulatory shunts or simple diffusion. Although the physiological role of CRF in the peripheral autonomic nervous system will require further study, the presence of the peptide and its functional receptors in the adrenal medulla and sympathetic ganglia suggest that CRF regulates the activity of the peripheral autonomic nervous system. These findings are consistent with the notion that CRF has a major role in the integrated response of the organism to stress, with actions at all levels of the neuroendocrine effector system.

We thank Robin W. Stull, Charles Grewe and Thomas P. Tomai for technical assistance.

IgE-mediated degranulation of mast cells does not require opening of ion channels

M. Lindau* & J. M. Fernandez

Department of Membrane Biophysics, Max-Planck-Institut für biophysikalische Chemie, D-3400 Göttingen, FRG

Rat peritoneal mast cells respond to antigenic stimulation by releasing histamine through exocytosis. The dynamics of exocytosis can be investigated by dialysing single cells with patch pipettes using the whole-cell recording configuration of the patch-clamp technique[1,2]. However, dialysed cells fail to respond to external stimuli such as compound 48/80 or antigens, suggesting that essential cytoplasmic components have been washed out. We have developed a new patch-clamp configuration in which the patch under the pipette tip is not disrupted but instead permeabilized, preventing the diffusion of large molecules out of the cell. In this configuration the cell responds to external stimulation, and the capacitance as well as the conductance of the cell membrane can be recorded during degranulation. On antigenic stimulation, the cell capacitance (proportional to plasma membrane area), after an initial delay, increases by a factor of about 3. This increase in capacitance is often preceded by a transient increase in conductance. Agents that block Ca-activated channels inhibit this conductance change without affecting the amplitude and time course of degranulation. We therefore conclude that, in contrast to excitable secretory cells such as chromaffin cells[2], mast cells do not use ion channels in stimulus–secretion coupling.

When antigens were added to cells passively sensitized with immunoglobulin E (IgE), the cell being dialysed with the patch pipette did not respond and no inward currents were detected (less than 1 pA at +5 mV), whereas the surrounding cells degranulated within a few minutes (Fig. 1). This suggests that essential components had been washed out or inactivated by the pipette solution (Fig. 2*a*), breaking the chain between stimulus and exocytosis. The idea underlying the present work was to make the interior of the cell accessible not by disrupting the patch under the pipette by means of suction, but by permeabilizing it so as to create small pores. This would prevent the rapid diffusion of large molecules out of the cell (Fig. 2*b*) so that it would remain responsive to external stimuli.

Mast cells are permeabilized if the extracellular side of th plasma membrane is exposed to ATP^{4-} (ref. 3). When a pipett containing ATP, no calcium and a calcium chelator (EGT or bis(*O*-aminophenoxy)ethane *N*,*N*,*N'*,*N'*-tetraacetic acid BAPTA) was sealed against the surface of a mast cell, th membrane patch under the pipette became permeable and capacitive current transient could be measured in response t a voltage pulse (Fig. 1*c*, inset). As in the whole-cell configuratio the membrane capacitance (C_m) and conductance (G_m) of th cell as well as the access resistance (R_a) were derived from th transient. Typical values obtained were 200–5,000 MΩ for th patch access resistance (corresponding to ~200 Ω cm²) and plasma membrane resistance (R_m) of 20–100 GΩ (~20,000 cm²). The values for R_m and C_m (5–10 pF) agree very closel with the corresponding results obtained in the whole-ce configuration[1,4]. In a few cells the patch was disrupted, an measurements confirmed the previously obtained values. As th main difference between the standard whole-cell mode[5] and ou method is the time constant of the capacitive transient, w propose the name 'slow whole-cell' (C_mR_a ~10 ms) for this ne method, as opposed to the 'fast whole-cell' (C_mR_a ~100 µs obtained by patch disruption.

In the slow whole-cell configuration, mast cells degranula together with the neighbouring cells in response to extracellul stimuli such as compound 48/80 or multivalent antigens. Figu 1*c* shows a group of mast cells that had been passively sensitize with IgE. Recordings were made from one cell of the group i the slow whole-cell mode (capacitive transient shown in t inset). On stimulation with dinitrophenyl linked to bovine seru albumin (DNP$_{43}$–BSA), all the mast cells degranulated simu taneously (Fig. 1*d*). The capacitive transient did not change i amplitude but became about three times slower, indicating th the capacitance of the cell had increased about threefold witho a significant change in access resistance. A small increase i membrane conductance also occurred after degranulatio (increased steady-state current in inset of Fig. 1*d*). The resu shown in Fig. 1*c*,*d* supports the idea of a wash-out of essenti cellular components by the fast whole-cell method (Fig. 2*a*).

Permeabilization of the patch provides a new method f monitoring exocytosis in undisturbed, intact mast cells. W anticipate that this method will be applicable to other cell typ by the use of pore-forming substances, thus enabling t monitoring of events that require an intact cytosol. The slo whole-cell method is similar to microelectrode recording bu unlike the latter technique, causes little damage to the cells.

Figure 3*a* shows typical time courses of changes in the ce membrane capacitance and conductance following stimulatio with DNP$_{43}$–BSA. In the slow whole-cell mode, capacitan

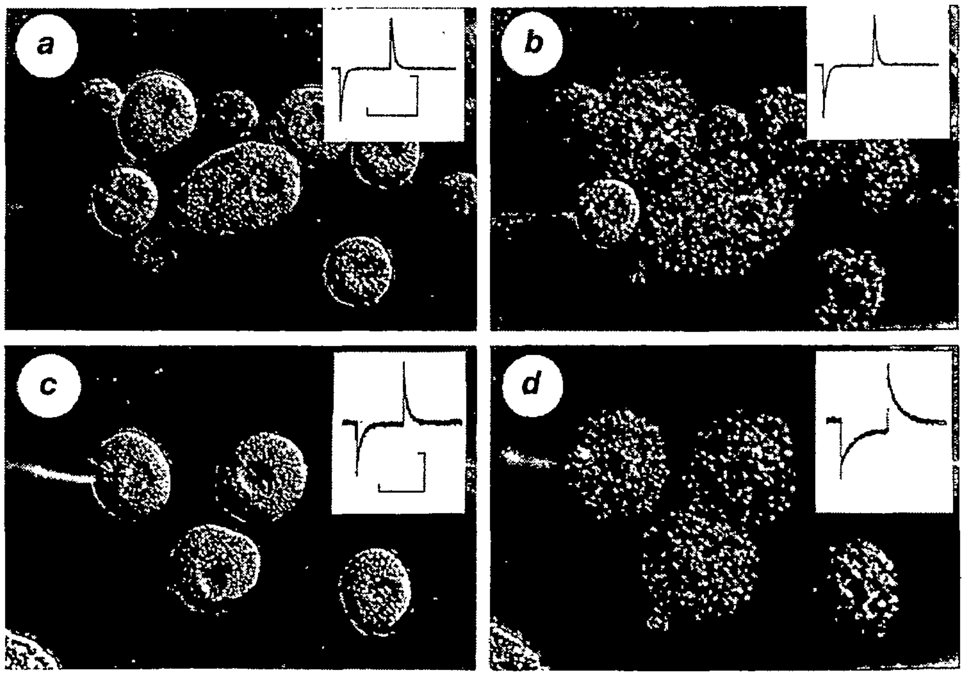

Fig. 1 Typical dispersions of cells from a rat peritoneal lavage. Mast cells are easily recognized by their large nucleus and granular appearance. The cells shown here were passively sensitized with monoclonal IgE before the experiment. *a*, A single mast cell in this group has been dialysed with our standard intracellular solution. Dialysis is accomplished in the whole-cell mode of the patch-clamp technique. In this configuration, a −20-mV voltage pulse (from 0 mV) induces a transient current (inset, calibration bars 1 ms, 2 nA), which corresponds to the charging of the cell membrane capacitance. The steady-state current is negligible due to the absence of ionic conductances in the mast cell membrane. *b*, On addition of DNP_{43}-BSA to the bath, all the mast cells except for the dialysed cell degranulate. The capacitive transient is also unmodified, implying that the membrane area, membrane conductance and pipette access resistance have not changed. Dialysis of rat peritoneal mast cells in these conditions thus renders the cells refractory to external stimulation, which suggests the loss of cytoplasmic components essential for stimulus-secretion coupling. *c*, A patch pipette containing a solution including 400 μM ATP and 400 μM BAPTA is sealed against one mast cell of the group. The membrane patch is permeabilized by this solution, allowing electrical measurements of the cell capacitance and conductance The inset shows the current transient in response to a −20-mV pulse (inset, calibration bars 100 ms, 10 pA). This transient is similar to the one obtained in the fast whole-cell configuration (*a*), but is about 100 times smaller and slower, as expected from the large access resistance R_a (see Fig. 2*c*). The resting cell parameters as determined from this transient are: $R_a = 1.9$ GΩ, $C_m = 6.3$ pF, $R_m = 34$ GΩ (29 pS). *d*, The same group of cells 5 min after addition of DNP_{43}-BSA to the bath. All the cells, including the one in slow whole-cell mode, degranulate simultaneously. The time constant of the capacitive transient (inset) is increased about threefold, but the amplitude is the same as in *c*, indicating an increase in the cell membrane capacitance by a factor of ~3, as expected from a degranulated cell. The steady-state current at the end of the pulse is also larger than before stimulation, indicating that the membrane conductance increased slightly. Cell parameters: $R_a = 1.9$ GΩ, $C_m = 18$ pF, $R_m = 7$ GΩ (140 pS).

Methods. The cells were incubated for more than 1 h with monoclonal IgE (1 μg ml^{-1}) at 37 °C before use. The chamber with the cells was mounted in the patch-clamp set-up and perfused with extracellular saline to wash off the unbound IgE. The external solution was then exchanged for a medium containing 145 mM NaCl, 2.8 mM KCl, 1 mM $MgCl_2$, 2 mM $CaCl_2$, 10 mM HEPES, 25 mM glucose, 100 μM phosphatidylserine. The pipette solution contained 150 mM K-glutamate, 10 mM HEPES, 7 mM $MgCl_2$, 200 μM Na_2ATP, 200 μM BAPTA. All solutions were adjusted to *p*H 7.2 with NaOH. A 20-μl aliquot of a solution of DNP_{43}-BSA in phosphate-buffered saline (100 μg ml^{-1}) was added in the vicinity of the observed cells to stimulate degranulation.

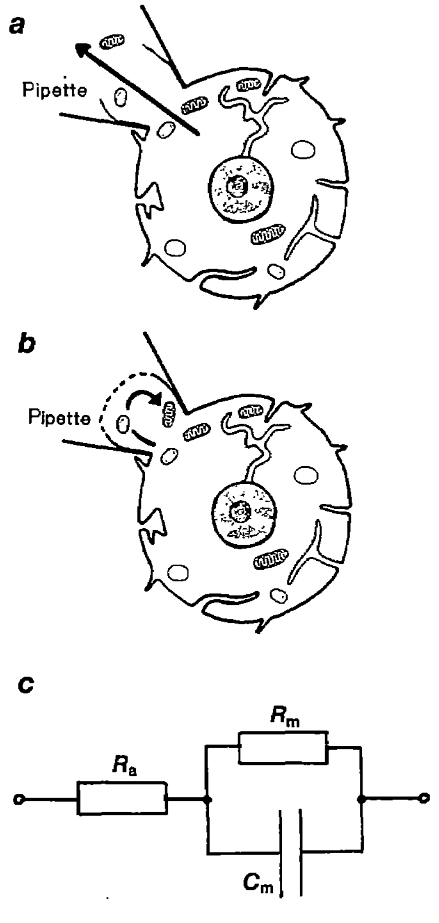

Fig. 2 Schematic representation of the fast and slow whole-cell configurations. *a*, Fast whole-cell configuration. The patch under the pipette has been disrupted by suction after seal formation. The diameter of the tip can be larger than 2 μm, allowing the diffusion of cytoplasmic components out of the cell volume (<1 pl) into the large volume of the pipette (~25 μl). *b*, Slow whole-cell configuration. The patch under the pipette is not disrupted but permeabilized, preventing the rapid loss of large cytoplasmic molecules and allowing the permeation of small ions. *c*, Equivalent circuit for both whole-cell configurations. The seal resistance between the interior of the pipette and the bath has been neglected. If a voltage pulse is applied, a capacitive transient is evoked which can be fitted by a single exponential. From the current response, C_m, R_m and R_a can be calculated. For mast cells, typical values are 5–10 pF for C_m and 20–100 GΩ for R_m, corresponding to a whole-cell conductance of 10–50 pS for a resting cell. The range of access resistance (R_a) is 1–20 MΩ in the fast whole-cell mode (*a*) and 100–5,000 MΩ in the slow whole-cell mode (*b*). If the current transient is recorded both in the slow whole-cell configuration and after patch disruption in the fast whole-cell mode, it is possible to determine the seal conductance. In these experiments the seal conductance was usually less than 15 pS.

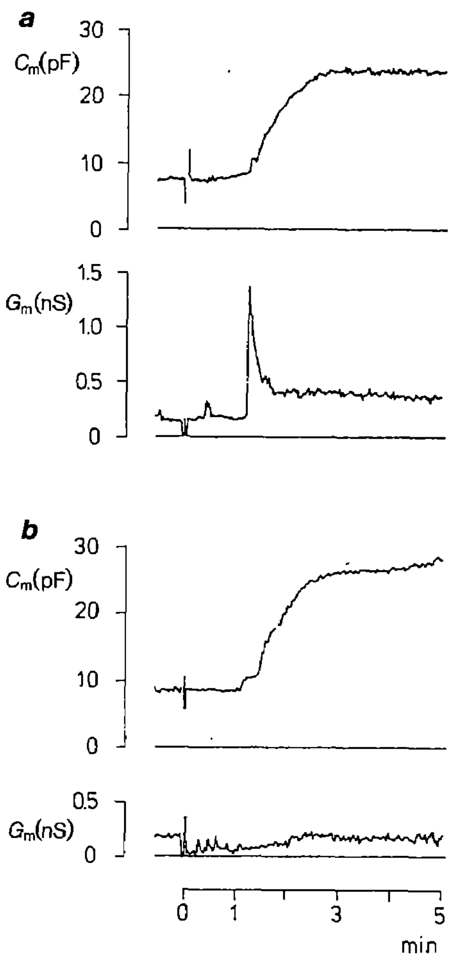

Fig. 3 Time course of capacitance and conductance of the mast cell membrane during IgE-mediated degranulation, recorded in the slow whole-cell configuration. *a*, Typical degranulation under normal conditions. Extracellular medium as in Fig. 1. DNP_{43}-BSA was added to the bath at time zero, causing the artefacts in the traces. The capacitance increased by a factor of ~3 after an initial delay of ~80 s (upper trace). The capacitance increase was preceded by a conductance transient of ~1.3 nS (lower trace). It probably corresponds to the opening of Ca-activated ion channels induced by a transient rise in the intracellular free calcium concentration. However, such transients were not observed in all cells. *b*, Degranulation in the presence of 10 μM pimozide (a gift from Janssen Pharmaceuticals). External solution as in Fig. 1, but containing 10 mM $CaCl_2$ and 10 μM pimozide. Pimozide was added from a 10 mM stock solution in ethanol. The time course and amplitude of the capacitance increase (upper trace) were similar to those shown in *a*. However, no significant conductance change was observed before degranulation. The addition of DNP_{43} was accompanied by a conductance decrease from 180 to ~50 pS in this experiment, probably due to an accidental improvement in the seal resistance. The following slow conductance increase is superimposable on the capacitance change, suggesting that the conductance increase simply reflects the increase of membrane area with a constant conductance per unit area. These results provide strong evidence that conductance changes are not necessary to activate exocytosis in these cells.

Methods. The increase of the membrane area during degranulation was monitored by measuring the membrane capacitance using the synthetic pseudo-random binary sequence (PRBS) method[6]. An 18-mV PRBS (128 bits long, 69 Hz bandwidth) was applied to the stimulus input of an EPC 7 patch-clamp amplifier (List electronics) operating in the voltage-clamp mode at a holding potential of 0 mV. The whole-cell current in response to the PRBS stimulus was sampled and stored by a PDP-11/23 minicomputer (Digital Equipment Corporation). The real part of the admittance was used to determine the capacitance C_m, the conductance $1/R_m$ of the plasma membrane, and the access resistance R_a. The d.c. conductance in *a* and *b* was determined by a fit of a quadratic function to the first eight data points at the low-frequency end of the admittance. After subtraction of this value, the frequency dependence can be linearized and C_m, G_m and R_a were then obtained by a linear least-squares fit. This procedure was carried out for each record (a record was taken every 1.8 s), giving the data points shown. The parameters obtained gave a good fit to the frequency dependence of the real and imaginary part of the admittance. All experiments were done at room temperature.

and conductance were determined every 1.8 s using a very low-frequency pseudo-random binary sequence technique (refs 1, 6; see Fig. 3 legend for details). After addition of DNP_{43}-BSA, the capacitance increased reproducibly by a factor of about 3 after a delay of 80±20 s (Fig. 3*a*). The half-time for the rising phase was 20–60 s. In most, but not all, cases, the capacitance increase was preceded by a transient conductance increase in the nanosiemens range (Fig. 3*a*, lower trace). At 0 mV holding potential, this conductance change was associated with only a slight shift of the current in the outward direction. We suspected that this conductance increase resulted from the elevation of the intracellular free calcium concentration, which could lead to the opening of Ca-activated channels that have been observed in the mast cell membrane[4]. This transient conductance increase was not always seen, but on the other hand, Ca-activated channels were not observed in all cells[4]. In the presence of either quinidine (500 μM) or pimozide (10 μM), which have been reported to block Ca-activated channels in other cell types[7,8], the extent and time course of degranulation were unchanged, as shown by the measurement of the cell capacitance (Fig. 3*b*, upper trace), but no significant conductance changes were observed before the onset of degranulation (Fig. 3*b*, lower trace). In these experiments the membrane conductance averaged 95± 75 pS ($n=4$) before degranulation started. The large scatter is probably due to different seal conductances. A small increase in the membrane conductance (from ~80 pS in the resting cell to 200 pS after degranulation; Fig. 3*b*) typically observed in parallel with the increase in capacitance, probably reflects the increase in membrane area. This suggests that the specific conductance of the granule membrane is not very different from that of the plasma membrane.

It is generally believed that the opening of Ca-selective ion channels is an essential step in stimulus-secretion coupling. For example, conductance changes in the range 800–2,000 pS are required for exocytosis in adrenal chromaffin cells[2], the increase in conductance resulting from the opening of Ca-selective ion channels. Accordingly, Ca channels might open in response to the crosslinking of the IgE receptors in mast cells[9,10]. In contrast to these expectations, our results show that rat peritoneal mast cells degranulate in response to antigenic stimulation without significant changes in membrane conductance.

Evidence for the entry of Ca as the main step in mast cell activation has been obtained from experiments showing that labelled Ca is taken up by degranulating mast cells[11], and that removal of extracellular Ca blocks antigen-induced degranulation[12]. However, the large increase in membrane area that occurs during degranulation can provide new binding sites for the labelled Ca, which may account for the Ca uptake observed[13] In our hands, the effect of removing Ca from the extracellular medium is time-dependent. If the cells are stimulated within 1 min of changing to a Ca-free extracellular solution, degranulation still occurs. Independence from extracellular Ca was also observed in experiments using intracellular Ca indicators which showed that mast cells stimulated 1 min after removal of extracellular Ca produced a significant intracellular Ca transient in response to antigens[14]. The long-term effects of the removal of extracellular Ca probably result from the unbinding of Ca from plasma membrane sites, which could damage the membrane components involved in stimulus-secretion coupling.

The results presented here, and the lack of effect of calcium antagonists[15] and of the removal of extracellular Ca at short times (ref. 14, also see above) argue against Ca entry as an obligatory event leading to exocytosis in mast cells.

We thank Dr H. Metzger for the gift of monoclonal IgE and its antigen, also Drs E. Neher, B. Sackmann, R. Eckert, M. Primke, A. Fahr and Mr J. Schroeder for discussions and comments on the manuscript. J.M.F. is an Alexander von Humboldt fellow.

lass I HLA (histocompatibility locus antigen) molecules are the argets of allospecific cytolytic T lymphocytes (CTL) in graft ejection, and constitute the restricting elements necessary for the nteraction between antiviral CTL and virus-infected cells. Cells xpressing only one HLA in the absence of other human molecules ould provide a remarkable model for studying the function of hese molecules. However, HLA^{+} murine cells transfected with uman genes[1–5] are generally not lysed by allospecific human TL[5–8], and this is ascribed to insufficient HLA expression, lack f human β_2-microglobulin, alteration of HLA molecules or bsence of receptors for human T8 or LFA1 molecules in murine ells[6–8]. Here we report, for the first time, the specific lysis of irus-infected HLA^{+} murine cells by HLA-restricted antiviral uman CTL. Therefore, these murine cells constitute an excellent odel for studying the role of HLA molecules.

Murine cells expressing HLA-A2 or HLA-A11 molecules have een obtained by transfection of P815-HTR cells[9] with genomic lones of well-established HLA specificities described preiously[10,11]. These cells were infected with the A/Texas (AT) uman influenza A virus and successful infection was ascerined in a control experiment in which the cells were specifically lysed by syngeneic anti-influenza murine CTL (data not shown). Uninfected HLA-A2^{+} and HLA-A11^{+} P815-HTR cells or untransfected P815-HTR cells were used as controls. Human anti-influenza A CTL of high efficiency were obtained from blood lymphocytes of donors after several *in vitro* stimulations with the virus, as described previously[12]. CTL from donor HC12 lysed the autologous infected cells (HC12-EBV-AT) and similar degrees of lysis were found with other infected HLA-A2 target cells, as illustrated here by one example (M17-EBV-AT). HLA-incompatible infected target cells (M10-EBV-AT) were not lysed, as determined in several control experiments. As shown in Fig. 1 (and confirmed in five different experiments), the same CTL lysed with high efficiency the murine HLA-A2^{+} cells (P815-A2-AT) infected with influenza A virus. In fact, a similar level of lysis was observed with both human and murine HLA-A2^{+} target cells. Uninfected HLA-A2^{+} control P815 cells (P815-A2) were not lysed, confirming the viral specificity of the cytolysis. Furthermore, P815-A2 cells infected with influenza B Singapore virus were not lysed (data not shown).

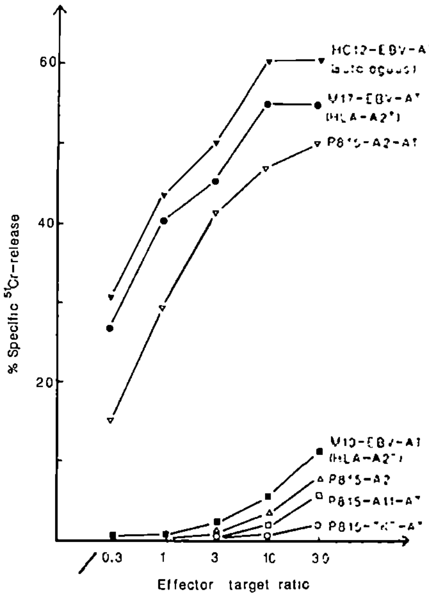

Fig. 1 Cytolytic activity of HLA-A2-restricted anti-influenza A human CTL on human or murine target cells. P815-HTR cells were transfected with either an HLA-A2 genomic clone[10] by the calcium phosphate DNA precipitation method[18], or an HLA-A11 clone[11] by the method of protoplast fusion in suspension[19]. HLA expression was ascertained by immunofluorescence using a monomorphic HLA-specific monoclonal antibody (B9.12.1). Lymphoblastoid cell lines were used as human target cells, as they are suitable targets and are easily infected with influenza virus[12]. The target cells were autologous (HC12), HLA-A2-compatible (M17) or HLA-incompatible (M10) with the effector cells. Effector cells were obtained from an HLA-A2 donor (HC12) whose peripheral blood lymphocytes had been stimulated three times *in vitro* with influenza AT-infected autologous lymphocytes in the presence of interleukin-2, as described previously[12]. The background lysis of target cells alone was between 20 and 24% for P815 cells whether infected or not, and between 15 and 26% for the human LCL target cells. The ^{51}Cr-release test was performed after incubation at 37 °C for 4 h.

To examine whether the lysis was HLA-restricted, untransfected infected P815-HTR cells (P815-AT) and HLA-A11^{+} infected P815-HTR cells (P815-A11-AT) were tested with human HLA-A2-restricted virus-specific CTL. These cells showed no lysis (Fig. 1). However, aliquots of P815-AT and P815-A11-AT cells were lysed very specifically by either murine anti-influenza CTL or murine anti-H-2^{d} CTL (not shown), confirming that these targets were virus-infected and lysable. Unfortunately, it was not possible to test HLA-A11-restricted human CTL, as HLA-A11 is a poor restricting element of anti-influenza responses in

Table 1 Treatment of effector cells with anti-T3, anti-T4 or anti-T8 monoclonal antibody (MAb) plus complement (C)

Treatment of effector cells	% Specific ^{51}Cr-release by: M17-EBV-AT	P815-A2-AT
—	37	41
Anti-T3 MAb+C	<2	2
Anti-T4 MAb+C	36	40
Anti-T8 MAb+C	<2	<2

HC12 anti-influenza AT effector cells were incubated for 30 min at 4 °C with OKT3, OKT4 or OKT8 monoclonal antibody (Ortho) diluted 1:100, then rabbit complement (Behring Institut) diluted 1:20 was added and the mixture incubated for 45 min at 37 °C, after which the cells were washed and resuspended in test medium. The effector/target cell ratio (calculated for effector cells before treatment) was 0.5:1.

man[13]. However, we have demonstrated that an influenza A-specific human CTL clone from the same donor but restricted by HLA-DRw8 (ref. 14) did not lyse P815-A2-AT cells. Furthermore, uncloned anti-influenza CTL restricted by HLA-B27 did not lyse P815-A2-AT (not shown). These results show that the human CTL used here lysed the P815 target cells not only in a virus-specific but also in an HLA-restricted manner, and similar results have been found with different batches of human effector cells, including CTL obtained after secondary stimulation *in vitro* and before their establishment as a permanent cell line.

The T4$^-$T8$^+$ phenotype of the human anti-influenza A CTL has been well established. To further confirm this identity for the present study, the effector cells were treated with anti-T3, anti-T4 or anti-T8 monoclonal antibody plus complement just before the chromium release test. Treatment with anti-T3 or anti-T8 antibody plus complement either abolished or strongly decreased the cytolysis of P815-A2-AT by human CTL, while anti-T4 had no effect (Table 1).

The present results show that murine cells infected with influenza A virus and expressing the HLA-A2 heavy chain can be lysed by HLA-A2-restricted anti-influenza A CTL of human origin as efficiently as the relevant human targets. The interaction is clearly virus-specific and HLA-A2-restricted, and the effector cells belong to the T8 subset of T cells. These results are in contrast to the negative or marginally positive results of experiments reported recently by several groups, including ourselves, in which anti-HLA human CTL were tested on HLA-transfected murine L-cells[6-8]. The discrepancies between these results may be caused by a number of factors. First, P815 cells are intrinsically better targets than L-cells when tested with murine CTL and, more significantly, with human allospecific CTL directed against an HLA molecule expressed on the (transfected) P815 target; this has been observed with P815-HLA-A24 cells[15] and we have found that P815-A2 and P815-A11 cells are lysed quite specifically by human anti-A2 or anti-A11 CTL, respectively[16]. However, a good degree of lysis has been observed recently with L-cells expressing a high concentration of a variant HLA-A3 antigen[17], which suggests that quantitative rather than qualitative factors may limit the interaction of human CTL with murine target cells. Another point to consider is that antiviral responses have been studied in the present experiments. In such reactions, the HLA epitope involved may be different from the epitopes recognized in anti-HLA responses. Moreover, simultaneous recognition of both HLA (restricting element) and viral protein by the T-cell receptor(s) may result in higher affinity. On the whole, and in contrast to previous suggestions[6-8], it is clear that murine cells transfected with human *HLA* genes provide a suitable model for the study of the relationship between the structure and function of human HLA molecules.

We thank Drs H. Orr and P. Paul for providing HLA-A2 and HLA-A11 genomic clones, Dr A. Van Pel for the gift of P815-HTR cells, and Mrs J. Debie for secretarial help.

***Trans*-acting factors that mediate B-cell specific transcription of immunoglobulin genes have been postulated based on an analysis of the expression of exogenously introduced immunoglobulin gene recombinants in lymphoid and non-lymphoid cells. Two B-cell-specific, *cis*-acting transcriptional regulatory elements have been identified. One element is located in the intron between the variable (*V*) and constant (*C*) regions of both heavy and κ light-chain genes and acts as a transcriptional enhancer[1-6]. The second element is found upstream of both heavy and κ light-chain gene promoters. This element directs lymphoid-specific transcription even in the presence of viral enhancers[7-10]. We have sought nuclear factors that might bind specifically to these two regulatory elements by application of a modified gel electrophoresis DNA binding assay[11-13]. We report here the identification of a human B-cell nuclear factor (IgNF-A) that binds to DNA sequences in the upstream regions of both the mouse heavy and κ light-chain gene promoters and also to the mouse heavy-chain gene enhancer. This sequence-specific binding is probably mediated by a highly conserved sequence motif, ATTTGCAT, present in all three transcriptional elements. Interestingly, a factor showing similar binding specificity to IgNF-A is also present in human HeLa cells.**

Mouse and human light-chain promoters contain the octamer sequence ATTTGCAT approximately 70 base pairs (bp) upstream from the site of initiation[14,15]. Heavy-chain gene promoters contain the identical sequence in inverted orientation, ATGCAAAT, at the same position. This element seems to be essential for the efficient use of immunoglobulin promoters in B cells[5,7,15]. The high degree of sequence and positional conservation of this element as well as its apparent functional requirement suggests its interaction with a sequence-specific transcription factor. We have searched for such a factor in a B-cell nuclear extract by using a gel electrophoresis DNA binding assay with enhanced sensitivity. This assay, which is based on the altered mobility of protein-DNA complexes during gel electrophoresis, has been extensively used in equilibrium and kinetic analyses of purified prokaryotic gene regulatory proteins[11,12,16,17] and more recently to identify and isolate a protein

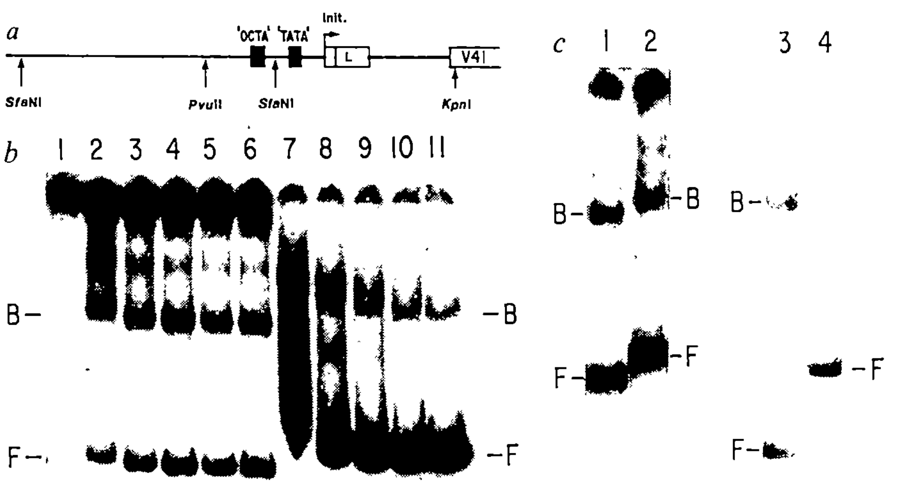

Fig. 1 Binding of a nuclear factor to the MOPC-41 κ promoter region. *a*, 5' region of the MOPC-41 V_κ gene segment. The 'OCTA' and 'TATA' elements start at positions −66 and −28, respectively. *b*, Gel electrophoresis DNA binding assays with the *Sfa*NI/*Sfa*NI κ promoter fragment (~300 bp). The *Sfa*NI fragment was subcloned into the *Sma*I site of pSP64 (pSPIgV$_\kappa$, provided by N. Speck). For binding analysis, this fragment was excised from pSPIgV$_\kappa$ by digesting with *Hin*dIII and *Eco*RI. These latter sites flank the *Sma*I site in the polylinker of pSP64. After end-labelling with [α-^{32}P]dATP and the large fragment of *E. coli* DNA polymerase I, the radiolabelled fragment was isolated by polyacrylamide gel electrophoresis. The ^{32}P-labelled fragment (~0.5 ng, 10,000 c.p.m.) was incubated with a nuclear extract[36] of a human B lymphoma cell line (EW[32]) in the absence (lane 1) or presence of two different non-specific competitor DNAs (lanes 2–11). Binding reactions (25 µl) contained 10 mM Tris-HCl (*p*H 7.5), 50 mM NaCl, 1 mM dithiothreitol, 1 mM EDTA, 5% glycerol and 8 µg EW nuclear extract protein. Reactions 2–6 also contained 800, 1,600, 2,400, 3,200 and 4,000 ng, respectively, of poly(dI-dC)·poly(dI-dC). Reactions 7–11 contained 300, 600, 900, 1,200 and 1,500 ng, respectively, of *Hin*fI-digested *E. coli* chromosomal DNA. After 30 min incubation at room temperature, the resulting complexes were resolved in a low-ionic-strength 4% polyacrylamide gel (acrylamide : bisacrylamide weight ratio of 30 : 1) containing 6.7 mM Tris-HCl (*p*H 7.5), 3.3 mM Na-acetate and 1 mM Na-EDTA[13]. The gel was pre-electrophoresed for 30 min at ~11 V cm^{-1}. Electrophoresis was carried out at the same voltage gradient for 90 min at room temperature with buffer recirculation. The gel was then dried and autoradiographed at −70 °C with a screen. F and B indicate positions of free and bound fragments, respectively. *c*, Binding assays as detailed in *b* using 2,400 ng poly(dI-dC)·poly(dI-dC) and the following DNA fragments: κ *Sfa*NI/*Sfa*NI (~0.5 ng, 10,000 c.p.m., lane 1), κ *Pvu*II/*Kpn*I (~0.5 ng/10,000 c.p.m., lane 2), κ *Pvu*II/*Sfa*NI (~0.1 ng, 5,000 c.p.m., lane 3) and pSP64 *Pvu*II/*Eco*RI (~0.2 ng, 5,000 c.p.m., lane 4). The κ *Pvu*II/*Sfa*NI fragment was derived from the plasmid pSPIgV$_\kappa$ by digesting with *Pvu*II and *Eco*RI. The *Eco*RI site is in the polylinker and therefore this fragment contains 16 bp of polylinker sequence.

that binds to satellite DNA from a nuclear extract of monkey cells[13]. In the latter study an excess of heterologous competitor DNA (*Escherichia coli*) was included with the specific probe fragment to bind the more abundant nonspecific DNA binding proteins in the extract. To minimize the binding of sequence-specific proteins to such heterologous sequence competitor DNA, we tested as a replacement the simple alternating co-polymer duplex poly(dI-dC)·poly(dI-dC).

A radiolabelled *Sfa*NI/*Sfa*NI DNA fragment derived from the upstream region of the MOPC 41 κ light-chain gene (Fig. 1*a*) was incubated with a nuclear extract of a human B-cell line in the absence or presence of two competitor DNAs. The resulting complexes were resolved from the free fragment by electrophoresis through a low-ionic strength, non-denaturing polyacrylamide gel and visualized by autoradiography (Fig. 1*b*). In the absence of competitor DNA, all of the labelled fragment was retained at the top of the gel (Fig. 1*b*, lane 1), probably due to the binding of an excess of non-sequence-specific proteins. With addition of increasing amounts of either poly(dI-dC)·poly(dI-dC) (Fig. 1*b*, lanes 2–6) or *E. coli* chromosomal DNA (lanes 7–11) as competitors, putative protein–DNA complexes which migrated more slowly than the free fragment were detected. The relative abundance of the major species of complex (B) as well as that of minor species was significantly greater in the presence of the alternating co-polymer competitor DNA. Because substitution of the simple co-polymer considerably increased the sensitivity of the assay, it has been used in all subsequent binding analyses.

To test the sequence specificity of the major species detected in the binding assay, a set of mutually overlapping κ promoter fragments (Fig. 1*a*, *Sfa*NI/*Sfa*NI, *Pvu*II/*Kpn*I and *Pvu*II/*Sfa*NI) and a similar-length fragment derived from the bacterial plasmid SP64 (*Eco*RI/*Pvu*II) were individually assayed (Fig. 1*c*). Whereas the bacterial DNA fragment showed no appreciable binding (Fig. 1*c*, lane 4), all of the κ promoter fragments yielded major discrete complexes of similar mobilities (lanes 1–3). We have found that the mobilities of a series of complexes formed with different-length fragment probes (75–300 bp) are approximately the same (data not shown). These data therefore suggested the binding of a specific nuclear factor within the region of overlap of the κ promoter fragments. This region includes the conserved octameric sequence but not the TATA element. Note that with the smallest 75-bp κ promoter fragment (Fig. 1*c*, lane 3), no appreciable label was retained at the top of the gel. Thus, as has been noted recently, the use of small probe fragments further enhances the sensitivity of detection of specific protein–DNA complexes[18].

The sensitivity gained by using both the co-polymer and a small fragment probe permitted the detection of two complexes, B1 and B2 (Fig. 2*a*, lane 1). The major species, B1, corresponds to complex B in Fig. 1. The relative affinity of the factor(s) for κ promoter DNA was estimated by a competition assay (Fig. 2*a*). Whereas a control plasmid (pSP64), when added in the above incubation, failed to compete for binding in the concentration range tested (Fig. 2*a*, lanes 2–4), the recombinant plasmid (pSPIgV$_\kappa$) effectively reduced the formation of both B1 and B2 in the same range (lanes 5–7). The latter plasmid was constructed by insertion of the upstream region of the κ promoter into pSP64. Assuming that the pSPIgV$_\kappa$ plasmid contains a single high-affinity binding site, these results suggest that the nuclear factor(s) responsible for B1 and B2 has at least a 10^4-fold higher affinity for its cognate sequence than for heterologous plasmid DNA (see Fig. 2*a* legend).

To determine if the factor(s) responsible for the formation of B1 and B2 is specific to B lymphocytes, a nuclear extract derived from human HeLa cells was assayed for binding to the κ promoter probe (Fig. 2*b*). Both B1 and B2 were generated at similar levels by the HeLa extract to those observed with B-cell extracts (Fig. 2*b*, lane 1); furthermore, both were specifically competed for by the pSPIgV$_\kappa$ plasmid (lane 2). Thus, HeLa cells also contain a factor(s) which binds specifically to the κ promoter upstream region.

DNase I footprint analysis was used to delineate at a higher resolution the binding domain(s) of factor(s) present in complexes B1 and B2[19,20]. To facilitate these studies, the binding factor(s) from B cells was partially purified by chromatography of nuclear extract protein on a heparin-Sepharose column. Most of the binding activity eluted in a 0.25 M KCl step fraction, giving an approximately fivefold purification (data not shown; see Fig. 3 legend). For footprint analysis, after incubation of the partially purified factor(s) with the κ promoter probe, sufficient DNase I was added to produce a partial digestion of the DNA. The B1 and B2 species were then resolved from free fragment by polyacrylamide gel electrophoresis. Bound DNA was eluted from both B1 and B2 bands and examined by denaturing polyacrylamide gel electrophoresis (Fig. 3, lanes 2, 3 and 2',

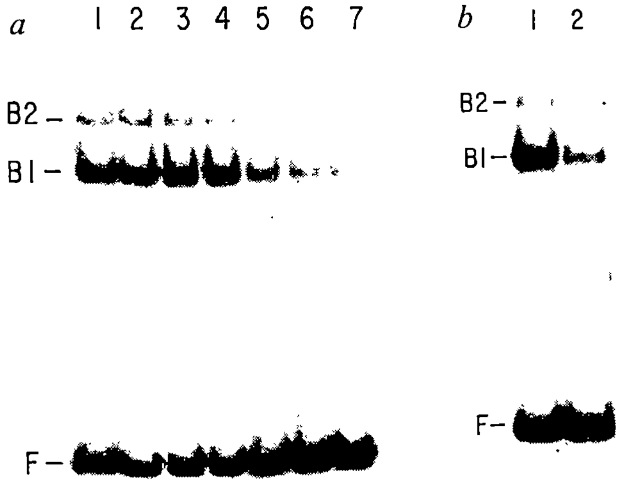

Fig. 2 Binding competition analysis in nuclear extracts of human EW and HeLa cells. ***a***, EW nuclear extract. Binding assays as detailed in Fig. 1*b* legend using radiolabelled κ *Pvu*II/*Sfa*NI fragment (~0.1 ng, 5,000 c.p.m.) and 2,400 ng poly(dI-dC)·poly(dI-dC). Reactions 2-4 additionally contained 50, 100 and 200 ng, respectively, of the bacterial plasmid pSP64 whereas reactions 5-7 contained 50, 100 and 200 ng, respectively, of the recombinant plasmid pSPIgV$_\kappa$. Assuming that a molecule of pSPIgV$_\kappa$ contains a single high-affinity site whereas a molecule of pSP64 (3,000 bp) contains 3,000 nonspecific sites, the apparent affinity ratio of the factor for these two types of sites is greater than $3{,}000\times200/50=1.2\times10^4$. ***b***, HeLa nuclear extract. Binding assays as detailed in Fig. 1*b* legend using radiolabelled κ *Pvu*II/*Sfa*NI fragment (~0.1 ng, 5,000 c.p.m.), 2,400 ng poly(dI-dC)·poly(dI-dC) and 6 μg HeLa nuclear extract protein[30] (provided by P. Grabowski). Reactions 1 and 2 additionally contained 100 ng of pSP64 and pSPIgV$_\kappa$, respectively.

3′). DNase I digests of the κ promoter probe in the absence of B-cell protein (Fig. 3, lanes 1 and 1′) and A+G chemical cleavage ladders were co-electrophoresed to map the binding domain. Factor(s) in the B1 complexes (Fig. 3, lanes 2 and 2′) appeared to protect a 19-nucleotide region on the coding strand. The 5′ and 3′ boundaries of the protected region map to positions −72 and −52, respectively, from the site of transcriptional initiation[3]. The region of DNase I protection was centred about the conserved octanucleotide sequence ATTTGCAT, suggesting its importance in the recognition of the immunoglobulin promoter by the nuclear factor. B2 complexes showed a virtually identical DNase I protection pattern to B1 complexes and therefore do not appear to involve additional DNA contacts (Fig. 3, lanes 3 and 3′). The simplest interpretation of this observation is that the B2 complex is generated by dimerization through protein-protein interactions of the factor responsible for the B1 complex. Alternatively, the B2 complex could be formed either by the binding of another protein to the factor responsible for the B1 complex or by recognition of the same set of sequences by a distinct DNA binding protein.

As the octamer sequence motif is present in both light- and heavy-chain gene promoters as well as in the enhancer elements of both mouse and human heavy-chain genes[15,21], we assayed for a factor binding to fragments from a mouse heavy-chain promoter (V_H) and the mouse heavy-chain enhancer. The V_H promoter fragment was derived from the 5′ region of the *V*17.2.25 gene and included nucleotides between positions −154 and +57 relative to the transcriptional start site[8]. In this promoter the conserved octanucleotide spans positions −57 to −50 (Fig. 4*a*). The heavy-chain enhancer fragment was derived from the germline joining-constant (J_H–C_μ) region and spanned positions 81–251 within a 313-bp region implicated in enhancer function[1]. The conserved octanucleotide is positioned between coordinates 166 to 173 in the above fragment (Fig. 4*a*). The B-cell heparin–Sepharose fraction (purified on the basis of binding to the κ promoter sequence; Fig. 4*b*, lane 1) produced a complex with both the V_H promoter fragment (lane 4) and the

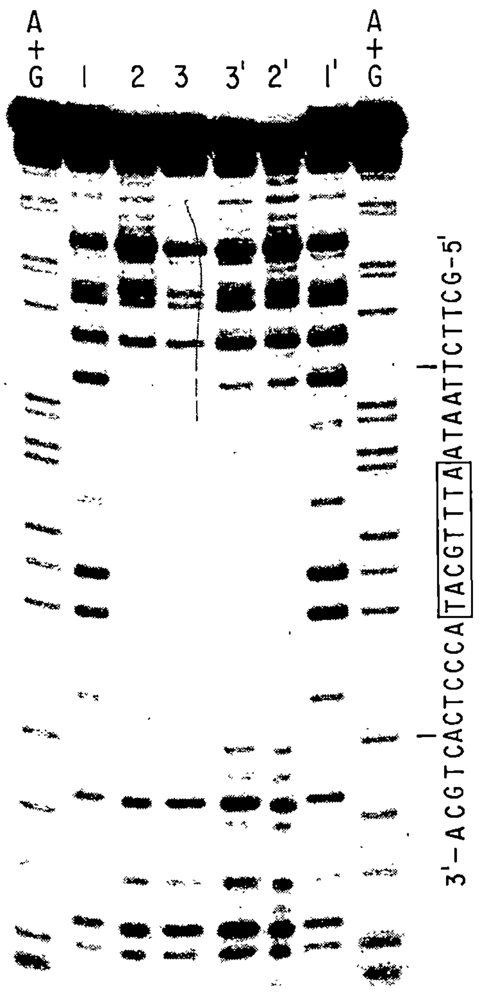

Fig. 3 DNase I footprinting of factor-DNA complexes. The B-cell nuclear extract was applied to a heparin–Sepharose column equilibrated with 20 mM HEPES *p*H 7.9, 20% glycerol, 1 mM dithiothreitol, 1 mM EDTA, 5 mM MgCl$_2$ and 0.1 M KCl. The κ-promoter binding factor was eluted with a 0.25 M KCl step. Binding reactions with this fraction (30 μl) contained 2.5 mM MgCl$_2$, κ *Pvu*II/*Sfa*NI (~1 ng, 100,000 c.p.m.) and 4,800 ng poly(dI-dC)·poly(dI-dC) in addition to components detailed in Fig. 1*b* legend. The coding strand of the κ promoter probe was 3′ end-labelled (*Eco*RI site) with [α-^{32}P]dATP using the large fragment of *E. coli* DNA polymerase. Reaction 1 was digested with DNase I (5 μg ml^{-1}) for 2.5 min at room temperature in the absence of B-cell nuclear protein. Reaction 2 was initially incubated with the heparin–Sepharose fraction of the EW nuclear factor (14 μg protein) for 15 min at room temperature and then digested with DNase I as above. Each reaction was stopped with EDTA (5 mM) and the products separated by native polyacrylamide gel electrophoresis as detailed for Fig. 1*b*. After autoradiography to visualize the various species, DNA was eluted from the free (reaction 1) and bound (B1 and B2, reaction 2) fragment bands by incubating gel slices in 0.5 M ammonium acetate (*p*H 7.5), 0.1% SDS and 1 mM EDTA with shaking at 37 °C overnight. The supernatants were extracted sequentially with phenol/chloroform/isoamylalcholol (25:24:1 v/v) and chloroform/isoamylalcohol (24:1 v/v) and precipitated with 2 vol ethanol in the presence of carrier transfer RNA. After a re-precipitation step, the products were analysed by separation in a 10% polyacrylamide gel (20:1) in the presence of 8 M urea followed by autoradiography at −70 °C with a screen. Lane 1 contains products of free fragment digestion from reaction 1. Lanes 2 and 3 contain digestion products eluted from bound fragment bands B1 and B2, respectively, from reaction 2. Lanes 1′, 2′ and 3′ correspond to 1, 2 and 3, respectively, except that the former set was digested with DNase I for 5 min. A+G chemical cleavage ladders[31] of the κ promoter probe were co-electrophoresed to map the binding domain.

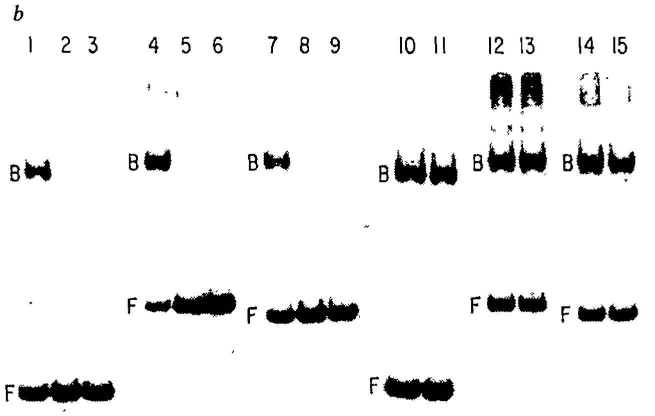

Fig. 4 Binding of a common nuclear factor to three immunoglobulin transcriptional control elements. *a*, Nucleotide sequences of actual and putative binding sites. The V_L binding site is defined by the DNase I protection assay (* indicates boundaries of the protected region). The V_H and J_H-C_μ sequence are putative binding sites in the *V*17.2.25 promoter[8] and the mouse heavy-chain enhancer[1], respectively. Numbers in parentheses indicate start coordinates of octamer motif. *b*, Binding competitions. Binding assays (10 μl) as detailed in Fig. 1*b* legend using 1,600 ng poly(dI-dC)·poly(dI-dC) and the heparin-Sepharose fraction of the EW nuclear factor (1.5 μg protein). V_L probe (~0.1 ng, 5,000 c.p.m.), lanes 1-3, 10, 11. V_H probe (~0.2 ng, 5,000 c.p.m.), lanes 4-6, 12, 13. J_H-C_μ probe (~0.2 ng, 5,000 c.p.m.), lanes 7-9, 14, 15. Lanes 2, 5, 8 additionally contained 5 ng of a V_L promoter oligomer (36 bp, spanning positions −81 to −44 of the MOPC-41 V_κ gene segment[3]) whereas lanes 3, 6, 9 contained 50 ng of the same oligomer. Lanes 11, 13, 15 additionally contained 50 ng of a J_H-C_μ oligomer that lacks the octamer motif (41 bp, spanning positions −1 to 40 of the heavy-chain enhancer[1,2]). Complementary single-stranded synthetic oligonucleotides were kindly made by Dr Ronald Mertz, Genzentrum der Universität München and Dr E.-L. Winnacker, Institut für Biochemie der Universität München. They were annealed before use as competition substrates in the binding assay.

enhancer fragment (lane 7). The mobilities of the complexes formed with the three fragments were very similar, consistent with the binding of a common factor. Furthermore, binding to these fragments was specifically competed for by a synthetic duplex 40-mer (Fig. 4*b* legend) that spanned the octanucleotide motif of the MOPC 41κ light-chain gene promoter (lanes 1-9). An oligomer of equivalent size containing a sequence from a region of the mouse heavy-chain enhancer lacking the octanucleotide motif (Fig. 4*b* legend) failed to compete for binding in the same concentration range (lanes 10-15). This competition analysis further strengthens the suggestion that a common nuclear factor (IgNF-A) binds to all three immunoglobulin transcriptional elements. As mentioned above these three transcriptional elements share an identical sequence motif, ATTTGCAT (Fig. 4*a*). Thus, the binding of a common nuclear factor is almost certainly mediated by this motif.

The use of a sensitive gel electrophoresis DNA binding assay in conjunction with the co-polymer competitor poly(dI-dC)·poly(dI-dC) has facilitated the identification of a putative mammalian gene regulatory factor. The simple alternating co-polymer probably competes less effectively than heterologous sequence DNA for binding of a sequence-specific factor, thereby significantly increasing the sensitivity of the assay. The synthetic co-polymer has proved similarly useful in the identification of other immunoglobulin enhancer binding factors (R.S. *et al.*, in preparation) and also a transcription factor that binds to an upstream sequence in the adenovirus major late promoter[22]. A further increase in sensitivity in this assay is obtained by the use of small DNA probes (<100 bp) which minimize nonspecific binding interactions in a crude extract[18]. Binding competitions and DNase I footprinting analysis can be used to test the affinity and sequence specificity of the protein-DNA complexes. In the future, relevant factors can be purified using this assay for structure-function analyses. Such an approach will greatly facilitate the elucidation of the set of DNA binding mammalian gene regulatory proteins.

The biological function(s) of IgNF-A and its biochemical mode(s) of action remain unknown. Since deletion or disruption of the IgNF-A binding site in immunoglobulin promoters significantly reduces the level of accurately initiated transcripts *in vivo*[5,7,15] and *in vitro* (R.S. *et al.*, in preparation), we propose that IgNF-A is a sequence-specific positive *trans*-acting factor. Its mode of action may be similar to the eukaryotic promoter-specific transcription factors Spl (refs 23) and heat-shock transcription factor (HSTF)[24].

The IgNF-A binding site seems to be a functional component of the B lymphocyte-specific immunoglobulin promoter[7]. For example, sequences from this promoter containing the IgNF-A binding site specify accurate transcription in B cells but not in HeLa cells. The role of IgNF-A in this B-cell specificity is unclear, since point mutations in the IgNF-A binding site have not been tested *in vivo* to determine whether this sequence is responsible for such specificity. IgNF-A may not be restricted to B cells, as a factor has been detected in HeLa cell extracts which generates complexes with similar mobilities and sequence specificity (as tested by competition analysis). However, further experiments will be necessary to show whether the factor in HeLa extracts is similar or identical to IgNF-A. Interestingly, the immunoglobulin octamer motif in the IgNF-A binding site has recently been shown to be present in the upstream region (about −225 bp) of vertebrate U1 and U2 small nuclear RNA genes[25-28]. More importantly, this element dramatically stimulates (20-50-fold) transcription of U2 snRNA genes in *Xenopus* oocytes[27,28]. Therefore, IgNF-A may be a constitutive activator protein that also functions in the high-level expression of U1 and U2 snRNA genes in vertebrate cells.

The presence of an IgNF-A binding site in the mouse heavy-chain enhancer is intriguing. It suggests the additional involvement of IgNF-A in enhancer function. Deletion of an 80-bp region of the enhancer containing the putative binding site reduces enhancer activity ~10-fold[1]. The occupation of this binding site, *in vivo*, has been inferred from the fact that the G residue in the enhancer octamer is protected from dimethyl sulphate modification only in cells of the B lineage[29]. Furthermore, IgNF-A also binds in a sequence-specific manner to the simian virus 40 enhancer (J. Weinberger, personal communication), which contains the immunoglobulin octamer motif[15], thereby strengthening the notion that the factor participates in enhancer function.

Activated human monocytes express the c-*sis* proto-oncogene and release a mediator showing PDGF-like activity

Current ideas about the mechanism of wound healing and the pathogenesis of atherosclerosis, pulmonary fibrosis and hepatic fibrosis suggest a central role for the mononuclear phagocyte in attracting and/or stimulating the proliferation of mesenchymal cells[1-5]. We demonstrate here that activated human blood monocytes, but not resting monocytes, release a mediator that attracts smooth muscle cells and cooperates with other mediators to stimulate fibroblast proliferation. This mediator is very similar to platelet-derived growth factor (PDGF): its chromatographic properties and chemical stability are similar to those of PDGF[6,7], it competes with ^{125}I-PDGF for binding to fibroblasts and it immunoprecipitates with anti-PDGF antibodies. In parallel, stimulated monocytes, but not resting monocytes, express the c-*sis* proto-oncogene, a gene coding for one of the PDGF chains[8,9], consistent with the concept that expression of the c-*sis* proto-oncogene may be involved in the ability of mononuclear phagocytes to modulate the accumulation of mesenchymal cells.

The idea that activated human blood monocytes release a mediator possessing PDGF-like activity evolved from the demonstration that blood monocytes can release a mediator that attracts smooth muscle cells (SMC) and cooperates with other mediators in stimulating fibroblasts to proliferate (Fig. 1). When activated, monocytes released into the media a mediator that attracted SMC in a concentration-gradient-dependent fashion. This was observed independently of the stimulus used; opsonized zymosan, immune complexes and lipopolysaccharide all activated monocytes to release this mediator in a time-dependent fashion, the activity increasing up to 4 h and then levelling off. In contrast, the release of SMC chemotactic activity by unstimulated cells was minimal. The release of the SMC chemotactic signal by stimulated monocytes was completely inhibited by cycloheximide (not shown), suggesting it was synthesized by monocytes in response to the activation stimulus. Following partial purification by carboxymethyl-cellulose and blue-Sepharose chromatography, the monocyte mediator with SMC chemotactic activity was also demonstrated to have growth activity for human diploid lung fibroblasts and BALB/c-3T3 fibroblasts. Importantly, the growth factor activity had characteristics of a competence factor, that is, although it did not by itself stimulate the growth of fibroblasts, it did so in the presence of the progression factor insulin. Furthermore, in all samples, this paralleled the chemotactic activity for SMC.

Table 1 Biochemical characteristics of the mediator released by activated monocytes

Conditions	% Activity
Heat (100 °C, 10 min)	80 ± 4
Acid (*p*H 2.5, 22 °C, 30 min)	63 ± 5
Reduction (2 mM 2-mercaptoethanol, 22 °C, 30 min)	0
Trypsin (5×10^{-6} M, 37 °C, 30 min)	24 ± 2

Monocytes were cultured with lipopolysaccharide B (LPS) for 24 h at 37 °C, and the supernatant was tested for SMC chemotactic activity as indicated in Fig. 1*a*. Before exposure to various treatments, the supernatant chemotactic activity was equal to 290 ± 37 chemotactic units. Aliquots (1 ml) were exposed to various experimental conditions and the chemotactic activity was quantified as the per cent activity before any treatment. Heat stability was evaluated by boiling the monocyte supernatant for 10 min, cooling to 23 °C and then testing for chemotactic activity. Acid stability was determined by dialysing 1 ml of the monocyte supernatant overnight against 0.5 M acetic acid, lyophilizing and redissolving it with HCl (to a final molarity of 10 mM) before diluting in culture media for testing for chemotactic activity. Sensitivity to reduction was evaluated by dialysing the monocyte supernatant overnight against 100 mM Tris-HCl *p*H 8.0; 2-mercaptoethanol was then added and the supernatant incubated for 30 min. The supernatant was then dialysed against culture medium overnight and tested for chemotactic activity. Sensitivity to trypsin was evaluated by adding trypsin (100 μg, Worthington) to 1 ml of monocyte supernatant. After 30 min at 37 °C, soybean trypsin inhibitor (200 μg, Worthington) was added and the supernatant tested for chemotactic activity. At the concentration used, the soybean trypsin inhibitor mixture with or without trypsin did not alter the activity of the original monocyte supernatant. All studies were performed in triplicate and the data are presented as mean ± s.d.

Although several biological compounds are known to be chemotactic for mesenchymal cells[10], only two, PDGF[11] and fibronectin[12], are known also to have growth-competence activity for fibroblasts. Mononuclear phagocytes produce fibronectin, but when the supernatant from activated monocytes was chromatographed on gelatin-Sepharose to remove fibronectin, none of the SMC chemotactic activity was removed. Furthermore, the chemotactic activity present in conditioned media was not inhibited by the addition of antibodies to fibronectin (not shown). Finally, the conclusion that this monocyte mediator possessing SMC chemotactic activity and growth-competence activity was not fibronectin is consistent with the finding that activated human blood monocytes release maximal amounts of the PDGF-like molecule within 4 h of culture but release significant amounts of fibronectin only after 48 h of culture[13].

Further evidence that this monocyte mediator is PDGF-like came from: (1) its behaviour following exposure to various conditions (Table 1); it was resistant to heat and acid, but was sensitive to proteolysis and its activity was completely abolished by reduction, suggesting that it required disulphide bonding for biological activity. (2) It displaced PDGF from its receptors on fibroblasts (Fig. 2). (3) When added to an anti-PDGF antibody, supernatant from activated monocytes as well as the partially purified factor displaced ^{125}I-PDGF from the antibody in a similar pattern to PDGF (undiluted supernatant from activated

---

* Present addresses: University of Minnesota, Minneapolis, Minnesota 55455, USA (P.B.B.); Hôpital Louis Pradel, 69394 Cedex 3, Lyon, France (J.-F.M.); Medical University of South Carolina, Charleston, South Carolina 29425, USA (G.R.G.).

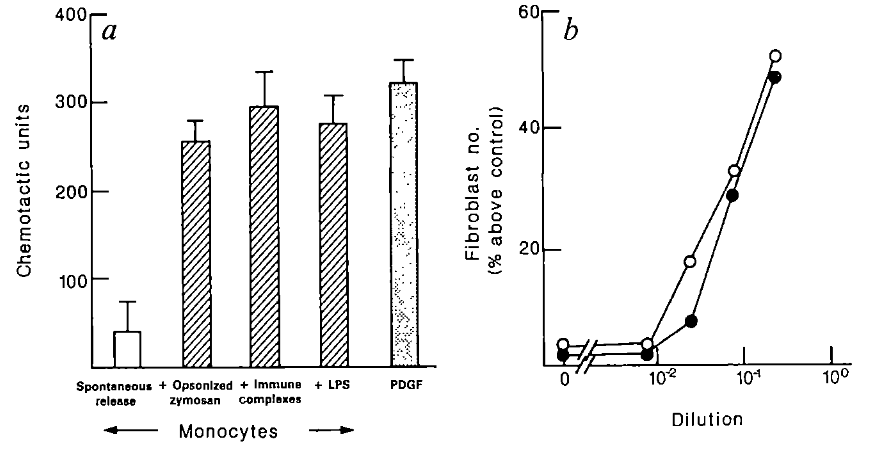

Fig. 1 Release of a mediator showing PDGF-like activity by activated human blood monocytes. *a*, Activated monocytes release a mediator possessing chemotactic activity for smooth muscle cells (SMC). *b*, Demonstration that the mediator with chemotactic activity for smooth muscle cells also exhibits PDGF-like growth activity for fibroblasts. The figure shows the number of fibroblasts (as % above the control of DMEM alone) with dilutions of the partially purified monocyte mediator (●) (starting concentration 50 μg protein per ml) or with dilutions of PDGF (○; starting concentration 25 ng ml^{-1}). Culture with the monocyte mediator alone, insulin alone or PDGF alone yielded no growth. All data points represent duplicates. Confirmation of the PDGF-like growth activity of the monocyte mediator was obtained by autoradiographic demonstration of ^3H-thymidine incorporation into nuclei of confluent BALB/c-3T3 (clone A-31; American Type Culture Collection CCL 163) in the presence of partially purified monocyte mediator and 50 μg ml^{-1} insulin (not shown).

Methods. ***a***, Monocytes were obtained by plating (plastic dish, 30 min, 37 °C) mononuclear cells isolated from blood by Hypaque–Ficoll centrifugation. Adherent cells (99% mononuclear cells, >87% monocytes) were cultured (4×10^6 cells ml^{-1}, 24 h, 37 °C) in Dulbecco's modified Eagle's medium (DMEM). In parallel cultures various stimuli were added: opsonized zymosan (zymosan A particles, Sigma; 10 particles per cell), immune complexes (human and rabbit anti-human albumin, Cappel; final protein concentration of 20 μg ml^{-1}) 1 LPS (*Escherichia coli* 0127; B8, Difco; 10 μg ml^{-1}). After culture (24 h, 37 °C), supernatants were collected and tested for chemotactic activity for SMC using a modified Boyden chamber[32]. SMC grown from explants of the medial layer of fetal bovine aortas[33] were suspended (4×10^5 cells ml^{-1}) in DMEM and placed in the upper wells; lower wells contained the supernatants to be tested. The filters (polycarbonate, 8 μm diameter pore size, Neuro Probe) were coated (72 h, 22 °C) with type V collagen obtained from human placental membranes. After incubation (4 h, 37 °C), the filters were removed, the cells were fixed and stained with Diff-Quik (American Scientific Products) and numbers of migrating SMC were determined[32] Each sample was tested in duplicate. The results (mean ± s.d. for 3 experiments) represent the value for each condition minus the chemotactic activity in response to DMEM alone. None of the stimuli by themselves had chemotactic activity. The attraction of the SMC by monocyte supernatants was demonstrated by checkerboard analysis to be concentration-gradient dependent, that is, chemotactic. Purified PDGF (5 ng ml^{-1})[34–37] was used as a positive control. For the monocyte supernatants, the data are presented as chemotactic units present in supernatant of 10^6 monocytes cultured for 24 h. ***b***, Monocyte supernatant obtained by culture of blood monocytes with LPS was dialysed for 48 h against 10 mM NaCl, 35 mM Na citrate, *p*H 7.0, and mixed overnight with carboxymethyl-cellulose (CMC, CM 52, Whatman). The CMC was then packed in a column, washed and eluted with a linear gradient (10 mM–1 M NaCl). The SMC chemotactic activity eluted with the front of the protein peak at 0.35 M NaCl. All active fractions were pooled and applied on a blue-Sepharose column (Affi-Gel Blue; Bio-Rad) which was eluted with 1 M NaCl, 35 mM Na citrate, *p*H 7.0, v/v ethylene glycol/H_2O. In parallel with SMC chemotactic activity, the growth activity for fibroblasts in this eluate was evaluated by a complementation test[11] using diploid human lung fibroblasts (HFL-1, American Type Culture Collection CCL 153)[38]. Non-cycling fibroblasts (culture in DMEM plus 0.4% calf serum for 4 days with an additional day in DMEM) were placed in DMEM with progressive dilutions of the blue-Sepharose eluate or PDGF in the presence of insulin (50 μg ml^{-1}; Collaborative Research). The fibroblasts were incubated for 3 days and then counted.

monocytes contained 10 ng ml^{-1} of the PDGF-like mediator; not shown).

The concept that activated monocytes release a PDGF-like mediator corresponds with the observation by Shimokado *et al.*[14] that activated macrophages secrete a PDGF-like molecule. Furthermore, it is consistent with various observations concerning the role of monocytes and their progeny in certain physiological and pathological situations. First, the classical description of wound healing includes the recruitment of monocytes to the wound, followed by the local accumulation and proliferation of mesenchymal cells. Consistent with the view that monocytes are central to this process, Leibovich and Ross[1] observed marked suppression of wound healing in animals depleted of mononuclear phagocytes. Second, in human fibrotic disorders, the accumulation and proliferation of mesenchymal cells and the subsequent formation of scar are invariably preceded by the accumulation of mononuclear phagocytes[4,5]. Third, animal models of atherosclerosis demonstrate the subendothelial accumulation of monocytes, followed by the recruitment of SMC and the development of the atherosclerotic plaque[2,3]. Finally, *in vitro* studies have shown that activated monocytes release 'monocyte-derived growth factor'[15], which possesses growth-competence activity for fibroblasts.

Since one of the PDGF chains (PDGF-2, B chain or peptide I) is encoded by the c-*sis* proto-oncogene (a gene on chromosome 22)[8,9], the fact that activated monocytes release a PDGF-like molecule suggests that monocyte activation is associated with the expression of c-*sis*. Consistent with this, we found that hybridization of monocyte poly$(A)^+$ RNA with a ^{32}P-labelled probe containing exons 6 and 7 of c-*sis* revealed the presence of a 4.2-kilobase (kb) c-*sis* messenger RNA transcript in activated but not in resting monocytes (Fig. 3). In contrast, using a probe for the γ-actin gene, we found that both resting and activated monocytes express the γ-actin gene 2.0-kb mRNA transcript, consistent with the knowledge that the γ-actin gene is expressed in all cell types[16].

The fact that human monocytes, when activated, express the

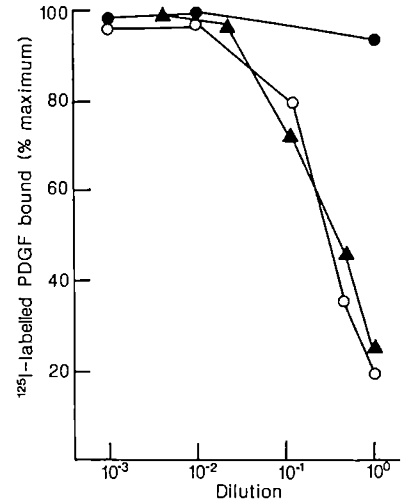

Fig. 2 Competition of the partially purified monocyte-derived factor with ^{125}I-labelled PDGF for binding to fibroblasts. Pure PDGF (1 μg) was labelled with ^{125}I using the chloramine-T procedure of Hunter *et al.*[39] and separated from free iodine by gel filtration on a PD-10 column (Pharmacia) previously equilibrated with 1 M acetic acid (titrated to *p*H 3.5 with NH_4OH) containing 1 mg ml^{-1} bovine serum albumin (BSA). The ^{125}I-labelled PDGF has a specific activity of 2×10^4 d.p.m. per ng. Receptor binding studies were performed as described by Heldin *et al.*[40]. BALB/c-3T3 fibroblasts (clone A-31; American Type Culture Collection CCL 163) were cultured for 5 days in DMEM with 10% calf serum in 24-well Falcon dishes (Becton-Dickinson) at which time they exhibited density arrest of growth. The cells were washed twice with binding medium (2 mM $CaCl_2$, 1 mM $MgSO_4$, 1 mg ml^{-1} BSA in phosphate-buffered saline (PBS)) and incubated with 5 ng (10^5 d.p.m.) of ^{125}I-PDGF containing: (1) progressive dilutions of non-labelled PDGF (○, starting concentration 1 μg ml^{-1}); (2) partially purified monocyte-derived factor (CMC, followed by blue-Sepharose, see Fig. 1*b* legend) (▲, starting concentration 400 μg ml^{-1}); (3) fibroblast growth factor (●, starting concentration 1 μg ml^{-1}, Collaborative Research) as a control After incubation (90 min, 22 °C) the cells were washed four times with washing media (2 mM $CaCl_2$, 1 mM $MgSO_4$, 1% calf serum in PBS) and lysed with lysing media (1% Triton X-100, 10% glycerol, 1 mg ml^{-1} BSA in 20 mM HEPES, *p*H 7.4). The bound ^{125}I-labelled PDGF activity was then quantified using a γ counter. All binding assays were done in duplicate; the data shown represent the mean values for three experiments.

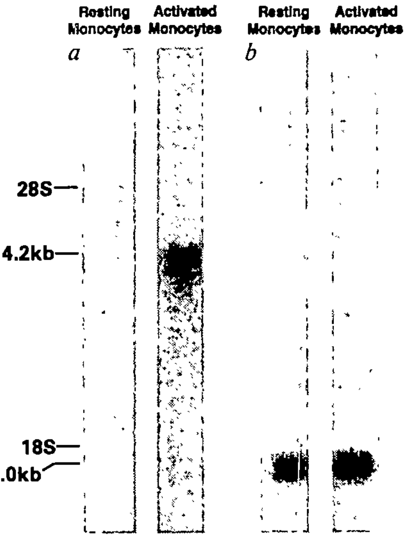

Fig. 3 Expression of the c-*sis* proto-oncogene in human monocytes. *a*, Presence of c-*sis* transcripts in activated monocytes; *b*, presence of γ-actin mRNA transcripts in both resting and activated monocytes.
Methods. Blood monocytes were cultured for 24 h with or without LPS (see Fig. 1*a* legend). After incubation, the cells were washed three times at 4 °C in PBS, *p*H 7.4, collected with a rubber policeman and pelleted by centrifugation (2,000*g*, 5 min). The cell pellet was homogenized in guanidine hydrochloride and subjected to ultracentrifugation through a caesium chloride cushion[41]. Total RNA was enriched for poly(A)$^+$ RNA by one cycle of oligo(dT)-cellulose affinity chromatography[42]. The poly(A)$^+$ RNA (5 μg each lane) samples were subjected to electrophoresis in a 1.1% agarose formaldehyde gel[43] and transferred to a nitrocellulose filter. The filter was hybridized with probes radioactively labelled with ^{32}P by nick-translation[44]. Hybridization and washing conditions were as described by Thomas[45]. RNA sizes were determined by comparison with human (28S, 18S) ribosomal RNA. The c-*sis* probe was clone pL335, a subclone of λ-L33 containing exons 6 and 7 of the human c-*sis* locus[17] kindly provided by E. Gelmann (NCI). The autoradiogram was exposed for 72 h. For *b*, the same filter as in *a* was used. After being allowed to undergo several half-lives of ^{32}P decay of the c-*sis* probe, the filter was hybridized to a human fibroblast cytoplasmic γ-actin cDNA (plasmid pHFγA-1)[46] kindly provided by L. Kedes (Stanford University). The autoradiogram was exposed for 8 h.

c-*sis* proto-oncogene in parallel with the release of a molecule showing PDGF-like activity is of interest in view of the known relationship of c-*sis* to the v-*sis* homologous sequences in the simian sarcoma transforming retrovirus[17], which induces NIH 3T3 fibroblasts and normal rat kidney cells to produce p28$^{v\text{-}sis}$ (ref. 18), a protein of relative molecular mass 28,000 showing close homology to one of the PDGF chains[19–21]. Since PDGF is a growth factor that induces its target cells to enter the G$_1$ phase of the cell cycle[11], the finding that a transforming virus contains sequences encoding a protein similar to one of the PDGF chains, and that the normal human genome contains sequences with >90% homology with p28$^{v\text{-}sis}$, has important implications for the initial events leading to malignancy. Consistent with these observations, a PDGF-like molecule has been detected in the culture media of human sarcoma[22] and glioma[23] and these cells express c-*sis* mRNA transcripts[24,25].

In addition to implications of the activation of c-*sis* for malignant growth, there is preliminary evidence that this proto-oncogene is involved in normal cell growth. In this context, cultured human and bovine endothelial cells express c-*sis*[26,27] and release a PDGF-like molecule[28], while rat arterial SMC release a PDGF-like protein[29]. Furthermore, using *in situ* hybridization, Goustin *et al.*[30] have recently demonstrated the presence of c-*sis* transcript in the cytotrophoblast of first-trimester human placenta in parallel with the release of a PDGF-like growth activity in the culture media. The present study extends these findings by demonstrating that c-*sis* proto-oncogene expression and release of a PDGF-like molecule occur in the activated human monocyte, a cell of major importance in scar formation and human fibrotic disorders as well as the early development of atherosclerotic plaque. These observations support the theory that common mechanisms are involved in the 'controlled' proliferation of cells involved in normal growth, the 'semi-controlled' proliferation of cells involved in the chronic inflammatory disorders, and the 'uncontrolled' proliferation of malignant cells.

We thank E. Gelmann, G. Wilding, N. Davidson and C. Agnor for help in carrying out this project and la Fondation pour la Recherche Médicale (for Y.M.) and Ministère des Relations Exterieures, France (for J.-F.M.) for partial financial support. *Note added in proof*: Since submission of this manuscript, Shimokado *et al.*[31] have also demonstrated that macrophages express c-*sis* and produce PDGF.

nature

British research scrutinized again

The House of Lords is to look again at the organization of British science. It could do worse than reprint its proposals on the same subject five years ago.

THE frequent complaint that the British parliament knows nothing of the conduct of science is a lie. Although the House of Commons is no better endowed with technical people than other elected legislatures, the House of Lords, for a quarter of a century dominated by people with only a life tenancy of a title, is a different kettle of fish. Five years ago, the Lords Select Committee on Science and Technology undertook an important study of how the British government runs research and concluded that affairs were badly managed. Now, with further experience bearing out that general conclusion, the same committee (with different people) is about to embark on essentially the same task, and is asking for opinions by 14 February (in writing) on the questions it has posed for itself. Here are shortened forms of the questions: the accompanying telegraphic answers are included for the convenience of readers too occupied with more urgent tasks (rewriting research grant applications, for example).

Q. *How far should public support for science and technology be an objective of national policy?* **A.** As far as a piece of string is long. All governments agree that there must be some public support; most know that an arbitrary degree of support will be justified by its consequences. The governments of France (see p. 165), Japan, West Germany and the United States, after five years of generous support for science and technology, are able to point to progress of the kind they promised; the British government, starting from the proposition that British science used to be a profligate business, can now claim as justification the fact that previously academic researchers have commonly become suppliants to industry for research funds.

Q. *Could the present division of responsibility between the research councils be improved?* **A.** What responsibility? The theory, at the time of the Rothschild report in 1971, was that the Science and Engineering Research Council (SERC, then significantly only SRC), is alone exclusively concerned with the welfare of academic research; the three other science research councils (the Economic and Social Research Council is in a dog-house all of its own) had specific remits for research in agriculture, medicine and the natural environment. They are goal-directed organizations, but their programmes range from basic research to some operational activity (geological survey, for example).

Much has changed in the past five years. Under financial pressure, the three operational research councils have been cutting back on their in-house research. (University people are also cheaper.) These councils appear also to have been genuinely moved by the condition into which British academic research has sunk, and are doing what they can to divert resources from their own establishments towards universities. When applied projects can usefully be carried out by academics, there is no complaint. One danger, probably not yet serious, is that there will be an awkward overlapping of criteria applied to basic academic research. Another, more immediate, is that the Agricultural and Food Research Council has probably now been weakened to the point at which it cannot do its job.

The Natural Environment Research Council (NERC) is in a different kind of trouble, never having been given a coherent job to do. The result is that it has a ragbag of functions, ranging from the support of academic earth science to the running of the British Geological Survey. The case for NERC's separate continued existence has vanished. (Lazy readers wishing to make the same point without being identified with the repetitious source of this opinion should either skip this question or say that the answer is "self-evident".)

Q. *What organizational changes are needed?* **A.** The fewest compatible with the survival of British research. There have been so many organizational changes so recently that stability would be welcome. Changes of substance are now more necessary than changes of form. But there is a need that some disinterested cabinet minister other than Mrs Margaret Thatcher should be asked to keep a watching brief on science, which is what the House of Lords committee recommended five years ago. Since then, the lack of political interest in science has patently allowed a once flourishing enterprise to be damaged, perhaps beyond repair.

If the case for a minister to look after science was strong five years ago, the intervening experience has only reinforced it. A strictly organizational benefit would be that the Advisory Board for the Research Councils, which exists merely to recommend a division of the annual science budget, would have a more pointed focus for its work. Subsuming NERC in other agencies would, by comparison, be a minor blessing.

Discerning readers will at this point recognize this question to be a trap. For all the constitutional importance of the House of Lords, it is not on this occasion bent on defending the entitlement of researchers in British laboratories to decent (let alone internationally competitive) salaries and other terms of service, but the personal penury that goes with a career in basic research will have to be tackled at some stage. What may worry the House of Lords (and should be keeping British researchers awake at nights) is the whiff of scandal that attends the quasi-autonomous conduct by British scientists of their own affairs.

Scandal? Nobody suggests that people have been stuffing public money into their pockets. The scandals that matter, and that damage science as well as the public purse, are more often errors of omission than of commission. There is, for example, the case of SERC's attempt, over four agonizing years, to reduce its spending on the infrastructure of astronomy: the committee charged with finding a solution, with the previous chairman of SERC at its head, has now apparently repeated the customary recommendation that nothing can be done. It seems not to be appreciated that indecisiveness on this scale plays into the hands of those in the British government, the Prime Minister in particular, who complain that basic research is effete. Maybe the new chairman of SERC, Professor Bill Mitchell, will be able to grasp the nettle that his predecessor has shrunk from, but the general question of how the research councils are managed needs attention. Professor Ralph Slatyer's argument (see *Nature* **319**, 3; 1986) in comparable Australian circumstances, that the chief executive should be the appointed servant of the policy-making council, should be compulsory reading for the House of Lords committee.

Q. *Are there other sources of funds than government for applied* *research?* **A.** Yes, but the question is badly put. Government spending on applied research is already substantial, chiefly through the government's own laboratories, especially defence laboratories; more should be spent by means of contracts with industrial and research organizations. What the House of Lords appears to have in mind is the possibility that industrial money from applied research might be used to prop up the research enterprise as a whole. Many universities have increased their incomes substantially by industrial contracts; the cost, in the diversion of creative people's interests, is not yet known. The chance that research council institutes may be able to save themselves by similar means is, however, much smaller.

Q. *How is the Rothschild principle working?* **A.** Not well at all, partly because the government that in 1971 enthusiastically welcomed the doctrine that applied research should be carried out by research councils, acting as contractors for customers identified as government departments, never gave the doctrine a chance. The notion that 10 per cent of the funds transferred in this way should be for basic research was never tried. Government departments have not been provided with chief scientists capable of operating the system, and have been free to renege on their commitments when it suited their convenience, causing mayhem in the research laboratories concerned.

Q. *Can defence research help civil research?* **A.** Yes, but only if the system is reorganized. The Prime Minister, Mrs Margaret Thatcher, and her now departed Defence Secretary, have never adequately delivered their promise, two years ago, to make defence research more open to British civil industry. Secrecy is only part of the problem. Lack of interest is a more serious obstacle. This is yet another reason why there should be a minister not merely to coordinate the government's spending on research but to develop a coherent policy on the subject.

The benefits of such a role are wider than mere coordination, although the value of a means of getting important questions decided cannot be underestimated. SERC may have procrastinated over the organization of astronomy, keeping those working at its establishments on tenterhooks, but the government is worse. Nothing has been heard of the proposal that Britain should bargain a reduced contribution to, or withdraw from, the European high-energy physics organization (CERN) since the government assumed responsibility from the Advisory Board for the Research Councils. Does anybody care what the consequences are for British academics, graduate students and potential graduate students who are vitally interested parties? On a smaller scale, but one not less vital for those whose careers are affected, the Ministry of Agriculture, Fisheries and Food has been brooding since last summer on an intelligent proposal that the Plant Breeding Institute, which develops new cereal varieties (among other things) should be joined in some manner to the National Seed Development Organization (which makes a profit for the Treasury by exploiting the same varieties. It is simply maladministration that these questions are neglected.

The question of money is important. The British government's policy for six years has been to keep the cost of civil science static. The enforced premature closure of once productive enterprises may have helped to balance the Treasury's books, but has otherwise been a diseconomy. It can only be a matter of time before the government (or its successor) has to change tack, and to behave like a spendthrift to undo some of the damage that has been done.

There is also the matter of people's morale to be considered. There is something in the belief that what is wrong with the British research enterprise is not the lack of money, serious though that may be, but the way in which continuing uncertainty has sapped people's belief that the research they do will be a foundation for even better things. In basic research, the time has gone, in Britain, when there was reasonable hope that modest beginnings could, if successful, grow into bigger enterprises. That is the sense that needs to be restored, more quickly than the supply of mere money. ☐

Agenda for Geneva

The resumption this week of the superpower talks is a time to ask what they can achieve.

As the Reagan–Gorbachev summit recedes in time, so do its problems. This week, the reassembly of the bilateral arms control negotiations at Geneva should bring them back abruptly. The US Strategic Defense Initiative (SDI) is bound to be high on the agenda; the summit participants agreed only to disagree about it. The first objective should be to prevent this divisive issue from wrecking the hard work that must be done on the control of strategic missiles. The second should be to confine the bargaining within the framework of what is realistically possible. Then, this year may even yield some tangible agreements.

This time, optimism is in order. That the summit happened, and did not finish up as a shouting match, is one good sign. That there is to be a second meeting later this year is another; the temptation to sign an agreement with some substance will be irresistible (especially with the mid-term elections in the United States just a few months off). But there is also a good chance that there will be progress in the multilateral talks at Stockholm; if some sting can be taken from the fear of a war in Europe, it should be possible for the stragetic negotiations to be flexible.

Finding a realistic framework for a year's work at Geneva will nevertheless be difficult. The Soviet Union and the United States, in the weeks before the summit, were talking about schemes for reducing strategic missile forces by about a half, but in terms that make each side's proposals unacceptable to the other. The Soviet plan has the added complication of counting as strategic missiles the French and British nuclear forces, over which the United States has no control. Attempting from Geneva to legislate for these missiles would be fruitless, at least in the immediate future. So the best strategy for the negotiators will be to adopt the goal of a 50 per cent reduction as one for 1987, and, during 1986, to aim at the more modest but attainable goal of putting the existing unratified agreement on strategic arms, SALT II, on a permanent basis that the US Congress will accept. Especially if there is some movement at the Stockholm negotiations, it should also be possible to deal with intermediate missiles by freezing them (with the proviso that the planned US deployment in Western Europe should be completed).

But why such a modest goal? Chiefly because a more ambitious agreement could not possibly be completed in the time available, but also because an agreement to make SALT II stick (it lapses in 1991) would force on the two governments concerned experience of the practical operation of arms control agreements which they at present lack. The idea that there should be regular meetings to discuss what missiles are where, and formal attempts to construct inventories of hostile forces, is unfamiliar. Operating such a system at strategic levels much like the present is a necessary preliminary. Aiming for a comprehensive test-ban now is similarly unrealistic. That is a task for 1988.

The complication of SDI should not be the obstacle public rhetoric suggests. The US administration insists that SDI is a means of making the world safe from the threat of nuclear weapons, the Soviet Union that it is a trick to make the United States alone immune from nuclear retaliation and therefore a provocation. If SDI is technically feasible, both views are tenable. But nobody can tell whether SDI is a realistic development programme or simply a technological mirage. The only reasonable technical prospect is that SDI will spawn, as a minor by-product, a satellite-borne warning system based on infrared detectors. So the Soviet interest would be met by an arrangement that the general character of SDI experiments beyond the atmosphere should be disclosed by a formal agreement to ban the development and testing of anti-satellite weapons and by the clarification and reaffirmation of the Anti-Ballistic Missile treaty. So much could be accomplished by the autumn of this year. ☐

French research strategy

CNRS embraces plans for research networks

THE French multidisciplinary research council, the Centre National de la Recherche Scientifique (CRNS), is learning to live on a static budget after a rapid period of expansion, its director-general Pierre Papon implied this week. This year's budget of FF8,000 million (roughly £800 million), although up by 8 per cent, will not be enough to cover the rising costs of keeping productively at work the 10,000 of France's most able researchers (10 per cent of whom are foreign) and the 15,000 technicians, engineers and administrators on CNRS's books. But CNRS does not intend to stagnate. Papon says that it will continue to move into new fields of research by adopting new methods of management and organization.

Papon's intentions make an interesting contrast with those of research organizations elsewhere, in Britain for example, similarly constrained by static budgets. Science minister Hubert Curien has effectively ruled out increased concentration of research resources on centres of excellence, saying that would be an unforgivable waste of research talent. This position is supported by Professor Frederick Joliot, science adviser to the prime minister, who argues that the US model for research support entails "excessive" competition, and that the French alternative, based on protected careers in research, allows greater freedom for the pursuit of long-term and speculative projects.

The key word in French science planning now is neither "selectivity" nor "concentration" but "networks", a term once fashionable at the European Commission in Brussels, but introduced in the context of CNRS by M. Curien just before Christmas. The intention is to link existing laboratories and their staffs into new projects, each lasting perhaps only a few years, to share staff and and equipment without a concomitant increase of costs.

So Papon and Curien intend that researchers should be more willing to change disciplines and that laboratories should be more open to others, both in France and elsewhere in Europe. Papon, for example, wants to create networks for the study and development of new materials, an approach that contrasts with the decision last year to set up a special laboratory devoted to one of the most fashionable of these, gallium arsenide.

Since 1981, CNRS has been creating new laboratories, usually linked with universities, at the rate of 20 a year, but last year there were only 10 and, during 1986, there will only "a few" additions to the present roster of 750 CNRS laboratories.

Even so, expansion will not be entirely halted. In what may turn out to be a last gesture towards expansionism, CNRS will build a dozen laboratories in the general field of information technology by the end of the decade at Marne la Vallée, a new town still under construction.

Growth will also be sustained by cooperation with regional governments, which now spend up to 3 per cent of their total budgets on research, and with industry. Thus, 1986 will see the beginning of a new metallurgy laboratory in cooperation with the company St Gobain and an inorganic polymer laboratory founded in conjunction with Rhone-Poulenc. But Papon insists that the work at the new laboratories will be basic and strategic — St Gobain, for example, is interested in metallic glasses — and that CNRS will not slip into the role of an applied research agency.

CNRS also intends in 1986 to create several "national laboratories" at which equipment and technicians will be provided only on condition that they are made available for use by other groups for a proportion of the time. An experiment on these lines in engineering science during 1985 is seen as a success and other disciplines are likely to follow in 1986.

During the year ahead, CNRS will have to find FF50 million for projects under the banner of Eureka, the European collaboration in high technology, out of the 8 per cent budget increase of FF700 million, but even so it will be able to increase spending on medium-scale equipment by 24 per cent, on minicomputers by a third and on large-scale equipment by 13 per cent. Spending on basic research materials will increase by 10 per cent in the life sciences, by 12 per cent in engineering and by 7 per cent overall.

CNRS intends to deal generously with some of its special programmes. Thus the budget of an interdisciplinary programme of materials research begun four years ago will increase by 58 per cent (to FF9.5 million), while there is to be a grand new programme (with a budget of FF11 million in the first year) to bring organic chemists and molecular biologists together.

CNRS will expand by a quarter its department concerned with the application of research, funds allocated to international cooperation are to increase by 13 per cent (international subscriptions are not included) and, in the scientific programme, there is to be more emphasis on the Earth sciences and oceanography (probably at the expense of astronomy); there is, for example, to be a new oceanography laboratory at Toulouse using remote-sensing data, particularly those from the SPOT series of satellites, not to mention a new programme of "cheap" communications research involving neurobiology, cognitive science, linguistics and artificial intelligence. Stasis does not mean to CNRS what it means to other people. **Robert Walgate**

Nuclear winter

Soviet researcher's part hyped

VLADIMIR Valentinovich Aleksandrov, the Soviet computer programmer who disappeared in Spain last March, was an "irreplaceable" Soviet scientist whose disappearance put an immediate end to East–West cooperation in the "mathematical modelling of global biosphere processes", in other words, research into nuclear winter, according to the Soviet weekly, *Literaturnaya Gazeta*. After a belated announcement by the Academy of Sciences (his employers) in December, which said little more than that he had disappeared, and a subsequent polemic in *Izvestiya* accusing the Central Intelligence Agency of having kidnapped him, *Literaturnaya Gazeta* devoted a full page to Aleksandrov and "nuclear winter".

By this account, Aleksandrov "is one of the scientists who have made the weightiest contribution to this field of research, thanks to which the consequences of a nuclear war have been placed before the entire world in an entirely new light, even more terrible than before". (He was in fact never more than a junior member of the Soviet teams to ENUWAR symposia discussing nuclear winter.) In the light of his lack of a doctoral degree, some Westerners have suggested that his place in the delegations may have been dictated by political rather than scientific motives; it is now claimed that he was too busy campaigning about nuclear winter, and that he was due to defend his doctoral thesis on 20 April.

According to his superior at the Computer Centre of the Academy of Sciences, Nikita Moiseev, despite his "comparative youth" (47), his election as a Corresponding Member of the Soviet Academy of Sciences was a foregone conclusion, although he has not been elected *in absentia*.

In one respect the paper is incorrect — international cooperation in "nuclear winter" studies was not "instantly broken" by Aleksandrov's disappearance. An ENUWAR symposium took place in June at the University of Essex, with a Soviet delegation clearly embarrassed by Aleksandrov's absence, to which it referred as a "tragedy". **Vera Rich**

German research agency

Ethologist takes the helm

Hamburg

PROFESSOR Hubert Markl, the distinguished ethologist from the University of Konstanz, is at 47 the youngest-ever president of the Deutsche Forschungsgemeinschaft (DFG), West Germany's principal agency for the support of basic research with federal government funds. Markl succeeded Professor Eugen Seibold, the geophysicist, at the beginning of the year. He has been elected as president for a period of three years in the first instance, having served as Seibold's vice-president.

Markl says that the appointment of one as young as he is "an experiment". On the telephone last week, he said that he regretted having to give up his university tasks and his scientific work for science administration, but that he was eager to fall in with the wishes of the members of DFG that he should be their president.

In his own way, Markl is somehow the representative of a new generation of scientists, and is endowed with remarkable optimism, dynamism and farsightedness. He says his most important tasks are "the justification of science to the public" and "the defence of the autonomy of science from which scientists cannot retreat".

Markl has strong views about the development of the university system in West Germany. On the contentious issue of the role of elite universities, Markl says that "one cannot simply copy systems that work well in other countries".

He sees no place in Germany for private elite universities, but instead looks for more competition between universities for good students. This, he believes, could lead to a system in which universities are distinguished by the fields in which they excel, with one being "top in agriculture, for example, another standing out for its chemistry". In this way, Markl says, "our scientific productivity will be used more effectively".

With the reduction of demand for student places now in prospect on demographic grounds, Markl believes that changes of the kind that he would welcome will come about automatically, especially as universities have more resources to devote to graduate education. He acknowledges that the age structure of university staffs in Germany is at present unsuitable, but hopes that DFG, with its annual budget of DM1,000 million, will be able to provide some relief. He is not especially alarmed at the risk that younger scientists will be sucked away to posts abroad, believes scientific exchange to be an important element of personal development, but says he would act to counter any threat of substantial loss of able people.

Markl has strong views on the social responsibility of science, which he says belongs not to "science as such, but to the individual scientist. Moral precepts never apply to abstract systems, but to the particular people who work for them."

He knows what he is talking about from his eventful life so far. Markl completed his doctorate (in Martin Lindauer's group at Munich) at the early age (by West German standards) of 24, and afterwards spent a year in the United States (at Harvard and the Rockefeller Universities). At the age of 29, then at Frankfurt, he completed his *Habilitation* (the formal qualification to hold a university professorship) as a zoologist, moving in turn to Darmstadt and Konstanz (in 1974).

Markl is likely to enjoy his spell as president of DFG, although his habit of saying what he thinks directly, even bluntly, could cause trouble from time to time. Markl recognizes the danger, saying that the years ahead will give him "a practical training in the applied ethology of science politics" and that "if I choose to walk through fire, I cannot complain of the heat". **Jürgen Neffe**

Seibold in Europe

Hamburg

PROFESSOR Eugen Seibold, who retired as president of DFG at the end of 1985, after serving two successive three-year terms, has been for many years one of the chief advocates in West Germany of international collaboration in research. A geologist by training, he was largely responsible for the development of the Geological Institute at the University of Kiel in the 1960s and 1970s.

Since the appointment last year of M. Hubert Curien as a minister in the French government, Seibold has been president of the European Science Foundation. In that role, he says, he will encourage the more rapid completion of the European Geotraverse, the deep seismic sounding of a dog-leg North–South section from Scandinavia to North Africa that is one of the foundation's chief projects. Jürgen Neffe

Antarctic treaty

Argentina expands research effort

ARGENTINA is to support its territorial claims in Antarctica by means of a major programme of research and geological exploration. According to the journal *Noticias Argentinas* last month, Argentina may also agree to an international system for the control of Antarctic mineral resources, but this, the paper said, would not prejudice Argentina's "reservations" about its sovereignty rights and maritime jurisdiction.

Argentina is alone among the seven countries that had laid territorial claims to the Antarctic continent before the 1959 Antarctic Treaty in still maintaining the apparatus of statehood there (including passport control). (It was partly the overlapping territorial claims of Britain, Chile and Argentina that led to the formulation of the treaty by which all claims to sovereignty were "frozen" until 1991.) Since the signing of the treaty, mineral wealth in the sector claimed by Argentina has been found to include chromium, nickel, cobalt, copper, gold, silver and iron.

Argentina maintains 16 bases on the Antarctic continent, including six permanent establishments, but only one of these has been engaged on scientific work. One result is that Argentina has carried out less scientific research than the other signatories of the treaty.

During 1985, Argentina sent 33 scientists, mainly geologists, to the Antarctic. In 1986, this number will be increased to 107 "scientists and technicians"; the possibility of opening a further base with a major airstrip is under serious consideration. The new emphasis on science is being presented as a "demilitarization" of Argentine Antarctic policy, although it is officially admitted that this will not mean a reduction in the logistic support provided by the Argentine armed forces. The (military) Argentine involvement in the Antarctic is said to cost some US $3 million a year. Partial "demilitarization" could make the effort partly self-financing, if Argentina sell equipment and services for Antarctic research and rents out its naval icebreakers for transporting scientific expeditions.

Official Argentine sources explain the need for the new policy by claims that New Zealand's "anti-nuclear" policy could lead to that country being used as a starting point for expeditions sponsored by the socialist bloc. There have also been unofficial indications that Argentina (and also its main Antarctic "rival" Chile) has been perturbed by the new "third world" interest in the Antarctic, demonstrated by the major expeditions by India and China which, it is considered, are operating far outside their own bailiwick.

The Indian position on this issue is, however, explicit; Antarctica is the southern boundary of the Indian Ocean, and may have an important influence on the monsoon and on the climate of India in general. China and Brazil, the two other recent recruits to the Antarctic Treaty, have less specific interests. **Vera Rich**

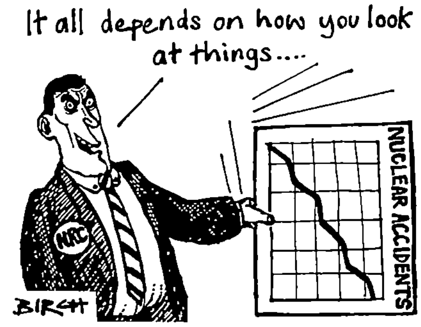
Nuclear safety

Opposition to relaxing standards

Washington

A ROW is brewing about the official calculations of the amounts of radioactivity likely to be released in nuclear accidents. The Union of Concerned Scientists (UCS) has added its criticisms to the reservations expressed last month by an advisory committee to the Nuclear Regulatory Commission (NRC) about the commission's proposed revision of "source terms" for nuclear power plants. These quantities refer to the probable amount and chemical form of radioactive releases to the environment in the event of a severe accident. UCS says the new source terms "deliberately" omit plausible accident sequences, including some that have actually occurred.

The new source terms are derived in a NRC draft report, NUREG-0956, and are inspired by research in the wake of the accident at Three Mile Island, some of which suggested that releases of radioactivity had been overestimated.



It all depends on how you look at things....
NRC
NUCLEAR ACCIDENTS
BIRCH

NRC's draft was criticized last month by its own Advisory Committee on Reactor Safeguards, which expressed "reservations" about the document and said the new source terms should "not be given much weight". Containment failure, an important factor in an accident, is treated, in a "rather preliminary fashion".

The NRC draft acknowledges the many uncertainties surrounding its estimates, and admits that the results depend critically on the design of particular plants. But externally initiated events, such as earthquakes, are not considered at all, according to UCS.

Although only five plants are modelled in the draft, NRC says it intends to go ahead and use the new source terms to re-evaluate and revise regulations governing power plant safety, from siting requirements to the design of safety systems. According to UCS, the revisions will in almost every case result in safety requirements being relaxed.

NCR's approach relies heavily on probabilistic risk assessment, which requires analysts to specify all possible routes to failure. Rupture of steam generator tubes, which has led to accidents in the past, is one omission cited by UCS, which has compiled a lengthy list of similar examples.

The UCS criticism comes at a bad time for NRC, which is investigating several accidents at nuclear plants that, according to Robert Pollard, UCS's nuclear safety expert and a former NRC official, occurred because NRC had not enforced its own requirements. The Toledo Edison Company may be fined $900,000 because of violations that led to an incident on 9 June last year, at its Davis–Besse plant in Ohio, when both main and auxiliary feedwater were lost. NRC has also upgraded its investigation of an accident in December at the Rancho Seco plant in California in which 450 gallons of contaminated water were spilled in an auxiliary building, leading to a small release of radioactive steam.

NRC says the UCS critique will be considered as a "comment" in its revision of NUREG-0956: a definitive report will be issued later this year. But Pollard doubts whether NRC will take notice "until we get them in court". How soon that will be depends of to what uses NRC puts its new source terms; but if the two do meet in court it will not be for the first time. Last time, UCS challenged NRC's right to restrict public comment on NRC rule-making. It won.

Tim Beardsley

Neutron research sources

US ambitions for new machine

Washington

COMPETITIVE juices are already rising in US laboratories hoping to capture a new advanced neutron source that they hope will be built during the first half of the next decade. Development funds for the instrument, which is seen as essential if the United States is to catch up with Europe on uses of slow neutrons, will be included in the Department of Energy (DoE)'s research budget for 1987, to be presented by the President to Congress next month.

Several recent studies requested by DoE have emphasized the European lead, which is ascribed largely to the success of the British/French/German collaboration at Institute Laue–Langevin in Grenoble in developing instrumentation for use in cold-neutron experiments. (Little account has yet been taken in the United States of the new British machine, the Neutron Spallation Source, commissioned last year by the UK Science and Engineering Research Council.) There is agreement that the immediate need is for a steady-state source producing up to 10^{16} neutrons $\mathrm{cm}^{-2}\mathrm{s}^{-1}$ (although the project would just get by with half-flux). Design concepts described at a recent workshop in Gaithersburg, Maryland, imply a facility costing about $300 million with running costs of about $25 million a year, although part of this could be saved by closing down one of the older sources when the new machine came on-line, according to Dr Donald Stephens, associate director of basic energy sciences at DoE.

Researchers are expecting about $6 million of development funds for the new machine in 1987. The most popular approach seems to be a 2–300 MW reactor source; Brookhaven National Laboratory is backing a design using small uranium oxide pellets, while Dr Ralph Moon of Oak Ridge National Laboratory wants a reactor with high-density uranium silicide fuel. A design suggested by Argonne National Laboratory, and disparaged as too preliminary by Moon, has rotating overlapping rings of fuel that would generate high flux densities near their point of contact and cool down during the rest of a revolution.

The chief technical problem foreseen for heavy water-cooled reactors operating at high power densities is in the formation of insulating aluminium oxide on fuel supports. Dr Robert Burke, of DoE's Hanford Engineering Laboratory in Washington state, favours instead a spallation design using a proton accelerator operating at a steady current of 100 mA. Burke says this approach would be more flexible than a reactor (because the protons could be used for other purposes) and that the less onerous safety requirements of an accelerator design mean that siting would be less critical. (He did point out that low electricity costs in the north-west Pacific would make this area attractive.)

The Hanford proposal would cost $300–450 million, according to Burke (although Moon says that $800–1,100 million would be nearer the mark), and he claims that the 100 mA proton-beam current required is feasible without extensive research. As a bonus, the Hanford design would allow the source to be upgraded easily should this be thought desirable.

For all the sparring over the design approaches, persuading Congress to build, or even to study, a new facility is not likely to be easy. But DoE's Energy Research Advisory Board has pointed out that existing major US neutron research facilities will be 30 years old by the time a replacement can be built, and the principal use of the new machine — neutron scattering — is the sort of research that can often bring immediate and tangible benefits. That might give it a better chance on Capitol Hill than the much more expensive facilities required for, say, high-energy physics.

Tim Beardsley

US/Canada acid rain

Envoys' compromise in dispute

Washington

A JOINT report on acid rain by US and Canadian special envoys met mixed reactions when it was delivered to the two governments last week. In Canada, there was a cautious welcome for the recognition that acid rain is a serious problem and that scientific knowledge is adequate to assess the effects of control strategies, but disappointment that no specific programme to reduce acid emissions was recommended. In the United States, President Reagan called the report a "step forward" and undertook to study it "carefully", but he avoided endorsing the principal recommendation that the US government should support half the cost of a $5,000 million programme to demonstrate new coal-burning technologies that minimize acidic emissions.

A Canadian government spokesman said that the report had "brought the acid rain question into the political arena, where it will be solved". Canada, whose tourism and fishing industries stand to lose from damage to lakes and forests, has long held that the scientific evidence justifies measures to reduce emissions from the tall stacks which are the principal sources of long-range pollution. Provincial governments in eastern Canada last year agreed with the national government that they will be responsible for reducing emissions of sulphur dioxide by 50 per cent by 1994. Automobile emissions of nitrogen oxides have also recently been brought into line with the more strigent US standard of 1 gram per mile. The US government, in contrast, has so far refused to acknowledge a link between acid emissions and environmental damage.

Richard Ayers, a lawyer for the Natural Resources Defense Council, says the report is a political compromise which nevertheless allows the utilities to delay action for another five years — well worth $2,500 million. But a more pessimistic view was offered by Adele Hurley of the Canadian Coalition on Acid Rain, who does "not expect to see the money".

The two special envoys, Drew Lewis (United States) and William Davis (Canada) were appointed last March to try to avoid a political impasse over the issue. There is no question that far more acid emissions find their way from the United States to Canada than in the opposite direction. The envoys say in their report that "it is very clear there is a solid link" between acid precipitation and emissions of acidic gases. Although clean-air legislation enacted in the United States in the early 1970s has improved ambient concentrations, long-distance transport (a result of tall smokestacks) has not improved.

The most widely used method of reducing emissions from existing plants, the scrubbing of flue gases, is expensive and produces enough waste to be a problem in its own right. New technologies that burn coal with increased efficiency and remove sulphur during combustion rather than afterwards, such as combined cycle gasification and fluidization bed combustion, offer a cheaper way to remove pollutants, but utilities say that they cannot be expected (because their tariffs are regulated) to risk huge sums on unproven technologies.

Meanwhile, the electricity utilities welcome the contention of the Lewis/Davis report that present scientific evidence is unsufficient to justify "punitive control". Industry spokesmen point out that utilities have already voluntarily spent $500 million on research into clean coal technology over the past 5 years, to be followed by another $500 million over the next 5 years.

The utilities' support for the envoys' recommendations is not altogether surprising because, if adopted, the recommendations would ensure that the US government pays half the cost of technology demonstration projects. The US Congress at the end of last year put $400 million into clean coal technology, but the industry has undertaken to spend up to $2,100 million if it gets a promise of support.

Some who have studied acid rain are less happy about the Lewis/Davis assessment that technology demonstrations are what is called for. David Schindler, who chaired a study on acid rain for the National Academy of Sciences in 1981, said he was "disappointed" that immediate control measures were not recommended and that the report concealed its true purpose of delaying action. Schindler said the evidence implicating sulphur dioxide in the acidification of lakes was "clearly strong enough" to support immediate action and stronger than the evidence on which the use of phosphorus in detergents was banned in the 1970s because of its effects on the Great Lakes.

Jack Calvert, of the National Center for Atmospheric Research, who chaired another National Academy study, said he had hoped the Lewis/Davis report would recommend a reduction in emissions from some of the major polluters in Pennsylvania, West Virginia or Ohio, so that actual effects could be observed and an informed decision taken on whether further controls are likely to be effective. Calvert applauded the report's support for greater efforts to monitor acid deposition, especially dry deposition, which is still not monitored systematically.

Whether the special envoys' work will lead to an easing of tensions between the United States and Canada over acid rain will now depend on the US administration's response to their recommendations, which include the setting up of a joint committee with a US cabinet-level representative.

The issue will be a "priority topic" at a meeting to be held in Washington in March between President Reagan and Canadian Prime Minister Brian Mulroney.

Tim Beardsley

Fusion research

US, Europe, Japan collaborate

IN an agreement signed yesterday (15 January), the United States, Europe and Japan, traditionally rivals in the search for economic energy from nuclear fusion, formalized a programme of enhanced cooperation in this direction. The agreement, signed at the Max-Planck-Institut für Plasmaphysik at Garching, Munich, commits scientists from the three programmes to hold regular trilateral workshops, to exchange basic data and experimental plans, and also personnel and equipment.

All three programmes are tokamak machines in which ionized hydrogen trapped in a toroidal container by magnetic fields may be heated to temperatures and densities sufficient for fusion reactions to occur. Basic heating is provided by passing a current through the torus, treating the plasma as a secondary winding in a transformer. But supplementary heating is required and, at all three tokamaks, is provided by a combination of high intensity radio waves generated from antennae in the torus walls and the injection of neutral atoms at high energy.

Present interest at all three tokamaks is in the development of the supplementary heating sytems; the problems of magnetic confinement and heating seem to have been solved. The heating system for Japan's JT–60 tokamak is expected to be working by next December, while at the Joint European Torus (JET) at Culham in Britain, the first stage of radio heating has been tested and neutral beam injection is about to be installed. Princeton's Tokamak Fusion Test Reactor (TFTR) is to embark this week on a lengthy experimental run.

According to Donald Grove of TFTR, the new agreement should make the three programmes more productive. "From now until the international fusion conference in Kyoto next November, the three tokamaks are on essentially the same footing", he says. It is hoped TFTR will achieve break-even in energy production, by means of deuterium fusion, by 1987.

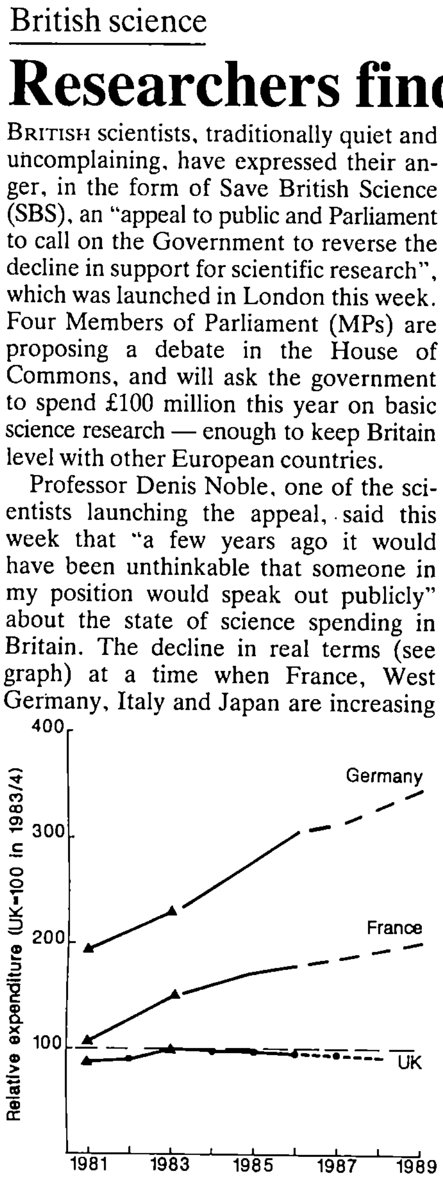
Philip Campbell

British science

Researchers find a voice

British scientists, traditionally quiet and uncomplaining, have expressed their anger, in the form of Save British Science (SBS), an "appeal to public and Parliament to call on the Government to reverse the decline in support for scientific research", which was launched in London this week. Four Members of Parliament (MPs) are proposing a debate in the House of Commons, and will ask the government to spend £100 million this year on basic science research — enough to keep Britain level with other European countries.

Professor Denis Noble, one of the scientists launching the appeal, said this week that "a few years ago it would have been unthinkable that someone in my position would speak out publicly" about the state of science spending in Britain. The decline in real terms (see graph) at a time when France, West Germany, Italy and Japan are increasing research spending, means that "selectivity is becoming a polite word for retreat, which is now in danger of becoming a debacle", according to Dr J. Mulvey, secretary of SBS. Noble described examples of scientists leaving to work abroad, obsolete equipment and occasions where scientists who had written successful grant proposals did not receive enough money for their own salaries, but only enough for the project itself.



Government funding of basic research in the United Kingdon, France and West Germany. Triangles, data from the *Annual Review of Government Funded R & D 1984* and *1985*. Dotted lines, policies based on recent ministerial reports.

SBS has collected more than 1,500 contributions since it was formed last November, and claims that grassroots support is "snowballing". But, apart from an advertisement in *The Times* about the predicament of British science, no coherent policy has yet emerged. Others have already pointed out the dangers of failing adequately to support basic science research to the government, with little success. The group must turn into efficient lobbyers for parliamentary support, and, as suggested by the MPs present at its launch, be both apolitical and efficient in communicating with the Government. SBS should have a formal membership so that it can genuinely reflect the wishes of its supporters and become an effective force in popularizing the need for research. It wants to obtain more support for research from industry, and thinks that government-induced collaborations between industry and academics are unlikely to produce more money for basic research whereas a tax-credit system for industries that fund this type of research is more likely to achieve the aim.

In Parliament, SBS could investigate the setting up of a body like the US Office of Technical Assessment, to advise MPs on scientific issue and to contribute to informed debate and wider general acceptance of the importance of science. A policy must also be formulated on whether or not Britain should have a representative at cabinet level specifically for science, or how seriously to take the Prime Minister's contention that she represents the interests of scientists.

Maxine Clarke

Refusnik scientists

Dissenting dissidents agree

Learned societies campaigning for oppressed scientists in the Soviet Union should avoid mentioning "human rights" in letters to the Soviet scientific establishment, Dr Alexander Voronel of Tel Aviv University told a seminar in Oxford this week. The seminar, for representatives of national academies of science and learned societies, had met to discuss what such bodies can do to help Jewish *refusnik* scientists. Although there were some vehement objections to Dr Voronel's view, notably from a delegate from the United States who described himself as an "academic lawyer", Dr Voronel's record as founder and first convener of the original Moscow Sunday seminar for *refusniks* gave his views considerable weight.

Dr Voronel's contention is that any mention of "human rights" is an automatic irritant to Soviet officialdom, which counters by alleging that the West is trying to interfere in internal Soviet policy. One should rather campaign, he said, for Soviet scientists to be allowed to exercise their professional rights of appropriate employment, unrestricted professional correspondence, participation in scientific gatherings both at home and abroad, and — the particular issues in the case of *refusniks* — the right to emigrate. This "right", incidentally, is now of paramount importance to the *refusniks;* a message to the seminar from three leading refusnik scientists, Victor Brailovskii, Mark Freidlin and Aleksandr Ioffe, urged all well-wishers "in view of the extreme urgency of our problem, [to] put aside all other aspects of our being here, and the difficulties encountered in our daily lives" and campaign only on the emigration issue.

Mr Fabian Kolker, the US philanthropist, who two years ago founded a scholarship for ex-*refusniks* at Tel Aviv University, summed up the views of both Voronel and the *refusniks'* letter. "Our goal should be success in unlocking the gates of the Soviet Union", he said, "and we must therefore use language that the Soviets will accept."

How to put more leverage behind such "language" was the main point of discussion. The chairman, Dr Inga Fischer-Hjalmars of the University of Stockholm presented an 11-point programme of suggested action, particularly slanted towards making intervention by Western colleagues a "professional" and not merely a humanitarian matter. Thus *refusniks* can be elected to the appropriate learned societies, or asked to join editorial boards of scientific journals, giving such societies or boards a valid interest in the welfare of and continuous contacts with their fellow members. (A suggestion from the floor extended this to asking *refusniks* to review books, which would have the additional bonus of supplying them with works in their field.)

If learned societies are to help, however, they must concern themselves, the consensus of the seminar agreed, not just with *refusniks* but with the whole range of breaches of human rights under all forms of repressive regime. This has always been a divisive issue, with Israeli scientists maintaining that one must not confuse *refusniks* and dissidents, while their foreign colleagues pointed out that it was impossible to ask a fellow faculty member to sign a petition on behalf of Brailovskii or Shcharanskii, and they refuse to sign the petition he was organizing on behalf of oppressed scientists in Turkey or South Africa. This time, however, there was little contention. It is now accepted, even by the Israelis, that learned societies and academics have human rights committees that campaign across the political board for scientists victimized for their convictions. Nevertheless, as Dr Kristoffer Gjotterud of Oslo pointed out, the distinction is a real one, and in campaigning for Soviet scientists in trouble, he stressed that one should never confuse the dissidents who wish to change what they see as inherent injustices in the Soviet system and the Jewish *refusniks* who are penalized for wishing to leave the Soviet Union altogether.

Vera Rich

Viral cancers

AIDS virus at the centre

Los Trois Ilets, Martinique

"RESEARCH in viral-associated cancers has come of age", said Peter Fischinger, deputy director of the National Cancer Institute (NCI) at a three-day conference here co-sponsored by the National Institutes of Health (NIH) and the Association pour la Recherche sur le Cancer (ARC).

Initial enthusiasm for the possible role of viruses in cancer accompanied the discovery in the 1960s that Epstein–Barr virus is associated with Burkitt's lymphoma. But that enthusiasm abated when little evidence was found to implicate other viruses with human cancers.

Today, the enthusiasm has returned. Nasopharyngeal cancer, a much more significant worldwide health problem than Burkitt's lymphoma, has also been linked to Epstein–Barr virus. Hepatitis-B virus DNA has been found in hepatocellular carcinomas. Different variations of human papilloma virus have been identified in 80 per cent of human papillomas, and, according to Harald zur Hausen of the Deutsches Krebsforschungszentrum at Heidelberg, it is likely that some form of human papilloma virus will be found in all forms of human cervical cancer.

Probably the most significant reinforcement of interest in cancers associated with virus comes from the discovery that a human retrovirus, HTLV-I, causes adult T-cell leukaemia, and that another human retrovirus, HTLV-III/LAV, causes acquired immune deficiency syndrome (AIDS).

In 1985, NCI spent $135 million on viral cancer research, approximately 12 per cent of its budget. Whether that level of support will continue is unknown. Both NCI director Vincent DeVita and NIH director James Wyngaarden were forced to bow out of this conference at the last minute to devise a new budget for NIH under the guidelines set forth in the recently passed Gramm–Rudman legislation (see *Nature*, **318**, 495; 1985).

Although HTLV-III/LAV has not been directly associated with cancer, the explanation may be that patients are killed by opportunistic infections seen in AIDS before cancers can develop. According to Max Essex of the Harvard School of Public Health, many more cats die from opportunistic infection associated with feline leukaemia virus than die from leukaemia.

A possible human parallel is seen in Japan; Isao Miyoshi of the Kochi Medical School reports seeing infections similar to those seen in AIDS patients in individuals infected with HTLV-I. There may be more of these patients, but so far no one has thought to look for them. Ironically, it may yet turn out that HTLV-III/LAV will cause cancer if AIDS patients can be kept alive long enough to exhibit it.

The explosion in AIDS research has produced several interesting and potentially important discoveries. Evidence for heterosexual transmission of HTLV-III/LAV continues to grow. In 1979, 12 per cent of AIDS patients in Haiti were female; now, the number has grown to 30 per cent, and is expected to grow to 40 per cent in the next two years.

Conflict continues about what constitutes an effective therapy for AIDS. Research at the Pasteur Institute in Paris has focused on HPA-23, a compound that can block HTLV-III/LAV production *in vitro* and apparently *in vivo*. Sam Brower of NCI believes that a therapy that blocks viral replication is insufficient, and that the need is for an agent that will restore the helper/inducer T cells destroyed by HTLV-III/LAV infection. One such compound appears to be 3′ azido-3′-deoxythymidine (AZT), now in clinical trials at NIH. A major advantage of AZT is it can be taken orally, an important consideration as it will have to be taken for life.

There are also indications that a new generation of assays for HTLV-III/LAV is not too far off. An important first step achieved in a preliminary form by Biotech Research Laboratories in Rockville, Maryland, is the purification of viral coat proteins, which may also play an important role in vaccine development.

There was some tension at the meeting between NCI and Pasteur Institute researchers over the recent lawsuit by the French over the granting of a patent for an HTV-III/LAV antibody test (see *Nature* **318**, 595; 1985). Both Luc Montagnier, the Pasteur researcher who first reported the association of a retrovirus with AIDS, and Robert Gallo, the NCI researcher whose work led to the US patent, attended the meeting. Nomenclature became somewhat confusing as the virus was alternately referred to as "HTLV-III/LAV", "LAV/HTLV-III", "LAV" or "HTLV-III" depending on the nationality and affiliation of the speaker. Future collaborations are not likely to suffer because of the current contretemps.

But Gallo complains of one unpleasant side effect of the lawsuit; he has been ordered to make photocopies of all notes and data relating to his work by US government lawyers acting in the lawsuit; this, Gallo maintains, will set back his research schedule.

ARC, the French co-sponsors of the meeting, have taken an active interest in viral associated cancers, especially in their relevance to health issues in underdeveloped countries. They also pride themselves on bringing together researchers around the world to tackle problems of mutual interest. In March 1984, a conference in Marseilles on cancers of the Mediterranean included Arab and Israeli researchers.

Says Gerard Milhaud, a member of ARC's scientific advisory board, "We got the Israelis and the Arabs together for a meeting. Bringing Montagnier and Gallo together was easy." **Joseph Palca**

Infection mechanism?

NCI's Robert Gallo now believes that transmission of HTLV-III/LAV infection is through cells, not virus particles. His scenario for spread of infection suggests that when a donor cell is recognized by a recipient cell, there is a mixed lymphocyte reaction. This in turn releases lymphokines which activate the initiating sequences of the viral genes, including the transactivating transcription gene (*tat*), which in turn causes viral expression in the newly infected host. This mechanism would explain why HTLV-III/LAV is not highly contagious, requiring some transmission of body fluid containing lymphocytes.

Gallo also reported five new cases of HTLV-II infection, and suggested there is some evidence that this virus is also spreading.

Although evidence for brain infection by HTLV-III/LAV is now undisputed, the exact target for infection is still in doubt. Luc Montagnier of the Pasteur Institute believes glial cells are infected directly, and has *in vitro* evidence to support this. Gallo, however, believes that brain involvement comes from monocyte macrophages migrating to the brain, possibly turning into microglial cells. Joseph Palca

Polish astronomers

THREE **Polish astronomers from the Copernicus Astronomical Centre in Torun are expected to go on trial this week for possession of an illegal radio transmitter. Drs Jan Hanasz, Zygmunt Turlo and Leszek Zaleski, all members of the Polish Astronomical Society, were arrested on 26 September, together with Mr Piotr Lukaszewski, a technician from a local factory, charged with an offence against public order and possessing the transmitter.**

They had used it to put out a television broadcast calling for a boycott of the forthcoming general elections, which they categorized as "undemocratic".

The astronomers last weekend called on Western colleagues to take note of their case, urging that, under prevailing conditions in Poland, the normal methods of making one's viewpoint felt were not available. Vera Rich

British veterinarians

Pressures for collaboration

The six British universities providing courses in veterinary medicine are in the throes of deciding how to meet the demand that they should teach fewer students and, at the same time, cost the central budget less. At a meeting on Wednesday this week, heads of the six schools and officials of the Royal College of Veterinary Surgeons will have tried to put a plan together. The University Grants Committee (UGC) is looking for a firm proposal by 28 January, and will otherwise draw up a scheme of its own.

The six British veterinary schools (at Bristol, Cambridge, Edinburgh, Glasgow, Liverpool and London) are all having to adjust to smaller student numbers in the wake of the third quinquennial report on veterinary manpower, commissioned by the Ministry of Agriculture, Fisheries and Food, which recommended a reduction of 10 per cent in the numbers of students recruited into veterinary medicine, from a total of 335 a year to just 300. These reductions will take effect from the beginning of the next academic year.

Pressure from UGC arises from the high cost of teaching veterinarians in Britain. Courses last five years, following the pattern of medical education, with three "undergraduate" years of biological science and two years of clinical study, including a compulsory 26 weeks of on-the-job training. Professor E.J.L. Soulsby (Cambridge), last year's president of the Royal College and thus the initiator of the present reform, points out that the teaching of veterinarians and physicians differs in that part of the cost of medical teaching is provided indirectly by the public health services, which keep the teaching hospitals full of patients and provide for their care. Many veterinary schools have to rely on private practitioners to supply sick animals, which must then be treated and cared for out of university funds.

Several alternative proposals for reorganization are being considered, among them a plan to allow the six schools to continue in their slimmed-down form for the first three years of the standard course, but to concentrate resources required for the succeeding years at different schools, with the understanding that students would move from one place to another.

Professor I.A. Silver (Bristol) says that if the six schools have not agreed on a plan this week, it will fall to the college (of which he is president this year) to put forward a scheme acceptable to UGC. He is heartened that UGC says it will pay close attention to the quality and the amount of research in deciding which schools should be favoured.

Not all veterinarians are reconciled to the conclusion that student numbers should fall by 10 per cent. Professor A. Iggo (Edinburgh) points to the potential value of novel biological techniques in the future treatment and management of domestic animals and thinks that the manpower estimates may take too little account of research needs. He reckons that a third of the income of his own department may arise from research grants and contracts.

Most British schools appear, however to accept that the overseas demand for veterinarians has shrunk substantially, even though there is still a buoyant demand from overseas schools from students with a first degree seeking graduate training and experience.

DNA fingerprinting

DNA probes control immigration

One of the first uses of the technique developed at the University of Leicester by Dr Alec Jeffreys for telling the genetic identity of individuals by the use of gene probes is likely to be in the control of immigration into Britain. But the Foreign Office denied last week reports from Dacca, Bangladesh, attributing to Mr Timothy Eggar, Under-Secretary of State, the announcement of the introduction of an operational scheme by April this year.

The issue is potentially contentious between Britain and Bangladesh, and between the British government and its immigrant population, because of the requirements of the now strict immigration law distinguishing between blood relatives of different affinity. What appears to have happened so far is that the Home Office and the Foreign Office are jointly sponsoring a pilot study at Leicester, but have not yet decided whether to mount an operational scheme for verifying claims of kinship.

Jeffreys says, however, that the technique has already been used successfully in a number of disputed immigration cases, the first of them on the initiative of a solicitor (attorney) acting for the father of an immigrant boy whose kinship had been disputed. The solicitor had been alerted to the usefulness of the techniques by publicity following the publication of a paper last March (Jeffreys, A.L., Wilson, V. & Thein, S.L., *Nature* **314,** 67; 1985: see also News and Views **318,** 507; 1985). The first analysis proved the claim of kinship, but the Home Office withdrew from the case so that there is as yet no legal precedent in Britain for the use of evidence of this kind.

Jeffreys says that the use of DNA fingerprinting in immigration cases is likely to be more complicated than in common paternity cases because disputed kinships may centre on suspicions that an adult is seeking to pass off a nephew as a son. Because of the high frequency of common genes among siblings, it is therefore necessary to test for a greater number of restriction polymorphisms. Even so, he estimates that it should be possible in routine cases to attain a precision of more than 99 per cent in cases of disputed kinship.

The Home Office emphasizes that even if the technique is introduced on a regular basis in considering applications for immigration to Britain, this will be offered only on a voluntary basis. (Nothing is said of the fate of those who decline a blood sample.)

Whatever happens to the immigration project, the forensic use of the technique is likely to be widespread. The commercialization of Jeffrey's version of DNA fingerprinting is being exploited by the Lister Institute.

Romanian mathematics

Absent guest at Princeton

Dr Radu Rosu, a Romanian mathematician invited to the Princeton Institute of Advanced Studies, last week began a 12-day fast to mark the beginning of the second term in which he has not been able to take up his invitation. Rosu, who was due to begin work at Princeton last September, claims that his application for a passport is blocked by the Communist Party organization of the University of Bucharest.

Dr Rosu, a geometer, began his research career at the Institute of Mathematics of the Romanian Academy of Sciences. When the academy was stripped of its institutes in the mid-1970s, and pure mathematics was virtually eliminated on utilitarian grounds, Rosu became a programmer at the computer centre of the Research Institute for the Energy Network.

In 1979, he transferred to the Institute of Mathematics at the university, where, in 1983, he successfully defended his doctoral thesis. The invitation to Princeton seems to have been inspired by a paper with Soviet mathematician I.M. Gel'fand.

Dr Rosu is not the only Romanian mathematician resisting his government's repressive policy. Last week, Dr Mihai Botez gave an interview on French television drawing attention to (and defying), the ban on unauthorized contacts with foreigners.

Vera Rich

Division of Japanese psychiatry

SIR—As the visiting scientist who drew the attention of *Nature* to the events surrounding the seventh congress of the Japanese Society of Biological Psychiatry in April 1985 (see *Nature* **315**, 361; 1985), I was interested to read the contribution of Dr K Moriyama (*Nature* **318**, 308; 1985) to the debate. As I understood the situation (from psychiatrists attending the meeting in Nagoya), it was indeed threats from the group with which Dr Moriyama is associated that led to the abandonment of the seventh congress, a satellite symposium on schizophrenia to be held in Gifu and then the *ad hoc* meeting organized in a hotel in Nagoya.

Two issues have emerged. Undoubtedly there are aspects of the Japanese mental health care system that are at variance with practice in other advanced nations. The report of the fact-finding mission of the International Commission of Jurists and International Commission of Health Professionals (see *Nature* **316**, 571; 1985) highlights a number of problems. One would expect that these would be the subject of discussion within and outside the psychiatric community in Japan and that someone of Dr Moriyama's declared interests would be working within a professional and political context (for example through a body such as MIND) for legal changes.

The second issue relates to freedom of exchange of scientific information. Dr Moriyama writes of "protest action taken against the seventh congress". Undoubtedly he and his followers have created a situation in which organizers feel obliged to cancel meetings rather than face confrontation. I understood from the psychiatrists to whom I spoke at the aborted meeting in Nagoya that previous "protest action" had ended in physical violence with the possibility of serious injury to meeting participants. A visitor to Japan has difficulty in understanding how Dr Moriyama and his colleagues justify adopting tactics that presumably are illegal, and finds it equally perplexing that the congress organizers did not consider the protection of the law adequate to allow the congress to continue.

Dr Moriyama alleges that the papers to be presented at the seventh congress reveal "evidence of many unethical experiments". I have a copy of the volume of 114 numbered abstracts that were to have been presented. These are mostly in Japanese, although the sections that are not indicate that the topics include many that were discussed at the recent World Congress of Biological Psychiatry in Philadelphia. I invite Dr Moriyama to indicate which abstracts he considers raise particular ethical issues. I will then arrange for these abstracts to be translated and submitted to a United Kingdom ethical committee (see for example Denham *et al.* 'Work of a district ethical committee', *Br. Med. J.* **ii**, 1042–1045; 1979) or to a comparable American institutional review board. It will then be possible to assess whether there is independent support for the views expressed by Dr Moriyama.

Animal intelligence

SIR—I should like to add to J.H. Fremlim's letter on animal intelligence (*Nature* **316**, 760; 1985). Human intelligence is not only quantitatively but also qualitatively different from animal intelligence because it recognizes time as a dimension. Man knows that there is a future in addition to the past and the present.

The awareness that a future exists gives man the incentive to plan, and to ensure that the plan succeeds. He therefore prepares weapons for the hunt and containers for the foraging expedition. This culminates in the discovery of agriculture, in the knowledge that seed planted in the spring will bring in a rich harvest in the fall, enabling him to survive the winter in comfort.

ANDREJS BAIDINS

1104 Windon Drive,
Wilmington, Delaware 19803, USA

Aleksandrov

SIR—Vera Rich writes (*Nature* **318**, 592; 1985) of "rumours circulating in the West" that Academician Vladimir Aleksandrov, who disappeared in Madrid last April, had been intending to defect, but was prevented by Soviet security men.

We no longer live in a time when every member of a Soviet delegation abroad is shadowed by another. Vladimir Aleksandrov, like many of his compatriots travelling in the West, had countless opportunities to defect. At a conference in Helsinki in 1984 I met him early one morning jogging in some woods — with nobody on his heels. And Western embassies in many capitals would surely be glad to give asylum to a leading Soviet mathematician and computer scientist.

It is also simply speculation to suppose that Soviet official silence on Academician Aleksandrov's disappearance indicates sinister goings-on. It is not Soviet policy to utter publicly on events that are bad news, unless it is to prevent their recurrence. Of course these rumours may be right, but where is the evidence?

STEWART BRITTEN

9d Stanhope Road,
London N6 5NE, UK

Creationism

SIR—In his Commentary on the unreasonable claims of scientific creationists, Michael Cavanaugh (*Nature* **315**, 185; 1985) seems to ignore the boundaries in biology that separate some observations from their causes and which are the basis for appealing to history, whether traditional or conjectured. Scientists have deciphered the genetic code, but chemical genetics has not supplied a theory for its origin. The stability of nuclear DNA has frustrated understanding how and from where organisms might acquire the enormous amount of genetic information needed to leap the persisting gaps in the fossil record — and on so grand a scale to bring whole populations into existence suddenly and worldwide. Cosmologists, too, recognize that the equations of the big bang theory are not capable of describing conditions before the big bang.

To assert in the absence of scientific theory that the origin of the genetic code and acquisition of new genetic information by organisms nevertheless occurred spontaneously is clearly a matter of faith. Evolutionists and creationists are therefore epistemological equals who are free to choose which history provides more meaning for life.

Creationists are indebted to evolutionists for having put the history of *Genesis 1* to the test. Practice of the scientific method has established boundary conditions concerning origins that are evidence for a creator. Along with evolutionists, creationists predict that these boundaries one day will open to rational thought.

California 92354, USA

Is anyone there?

SIR—There must surely be *something* magical about the "magic frequencies" at which, you report (*Nature* **317**, 275; 1985), yet another project is searching for extraterrestrial signals. But the magic is that anyone should waste their time, and our money, searching the bands where interference and attenuation of any such signals is at a maximum.

Any rational ET communication engineer would transmit at frequencies where these are at a minimum. Is anyone looking in the right place?

WHAT IMPACT ARE NEW BIOTECHNOLOGY TECHNIQUES HAVING ON MEDICINE WORLDWIDE TODAY?

Come to Nature's 7th International Conference in London on Molecular Biology in Medicine 1986 for all the up to date facts — and a look into the near future.

NEW TECHNOLOGY in BIOTECHNOLOGY

MOLECULAR BIOLOGY IN MEDICINE

a survey of its achievements and its potential

JUNE 18-20 1986 — LONDON

It is clear that the modern techniques of biotechnology are set to have a major impact on medicine. Over the next few years many new opportunities will emerge. This important conference will provide a wide-ranging survey of the most recent research in the fast changing field of molecular biology in medicine, and a look into the future. If you want an opportunity to see and hear for yourself what leading exponents have achieved in recent years — and to learn what new opportunities are on the horizon, come and join us. You'll find a booking form below.

JUST SOME OF THE NEW OPPORTUNITIES YOU CAN FIND OUT ABOUT FIRST HAND AT NATURE'S 7TH INTERNATIONAL CONFERENCE.

DIAGNOSTICS

Monoclonal antibodies to speed up and simplify laborious tests.

engineered antibodies to provide further sophistication.

gene probes to allow the detection of mutations that are linked to cancer.

THERAPEUTICS

the discovery of new families of proteins and peptides with potential clinical value.

the means to engineer proteins so as to improve their therapeutic value.

the use of monoclonal antibodies to target drugs to tissues.

PREVENTION

the first potential vaccines against several infectious diseases, such as malaria.

the refinement of existing vaccines.

the detection of genetic defects with sufficient confidence and speed to prevent or limit their damage.

AMONG THE LIST OF TOP CALIBRE INTERNATIONAL SPEAKERS WILL BE

G. Schild, National Institute for Biological Standards and Control, UK
A. Capron, Institut Pasteur, Lille, France
S. Gillis, Immunex, US
M. Neuberger, LMB, Cambridge, UK
L. Montagnier, Institut Pasteur, France
K. Sikora, Ludwig Institute, Cambridge, UK
R. Gerety, Merck Sharp & Dohme, US
T. Waldmann, NIH, US
R. Baldwin, Nottingham, UK
E. Tuddenham, Royal Free Hospital, UK
D. Weatherall, Oxford, UK
W.F. Anderson, NIH, US

OUR THREE DAY PROGRAMME ENABLES YOU TO ASSESS IMPORTANT NEW BIOTECHNOLOGY TECHNIQUES IN MEDICINE, MEET INTERNATIONAL RESEARCH SPECIALISTS, AND DISCUSS WHAT YOU LEARN WITH NEW CONTACTS FROM AROUND THE WORLD.

JOIN US AT NATURE'S 7TH INTERNATIONAL CONFERENCE, TO BE HELD AT THE LONDON WEST HOTEL, JUNE 18-20 1986.

REGISTER NOW TO ENSURE YOUR PLACE — SPACE IS LIMITED.

The **CONFERENCE FEE** is just £189 plus VAT for the three days of the conference. This includes entrance to all sessions, mid-morning coffee, afternoon tea and reading material. Group discounts are available on application to Janine Slipman, Macmillan Conferences and Exhibitions, 4 Little Essex Street, London WC2R 3LF, UK, Telephone (01) 836 6633.

Book before January 31st and we'll send you Nature's 1986 calendar FREE!

ACCOMMODATION has been reserved in the London West Hotel for conference participants. A booking form will be sent to you as soon as we receive your registration.

TECHNICAL SEMINARS and **POSTER SESSIONS** will be held each day.

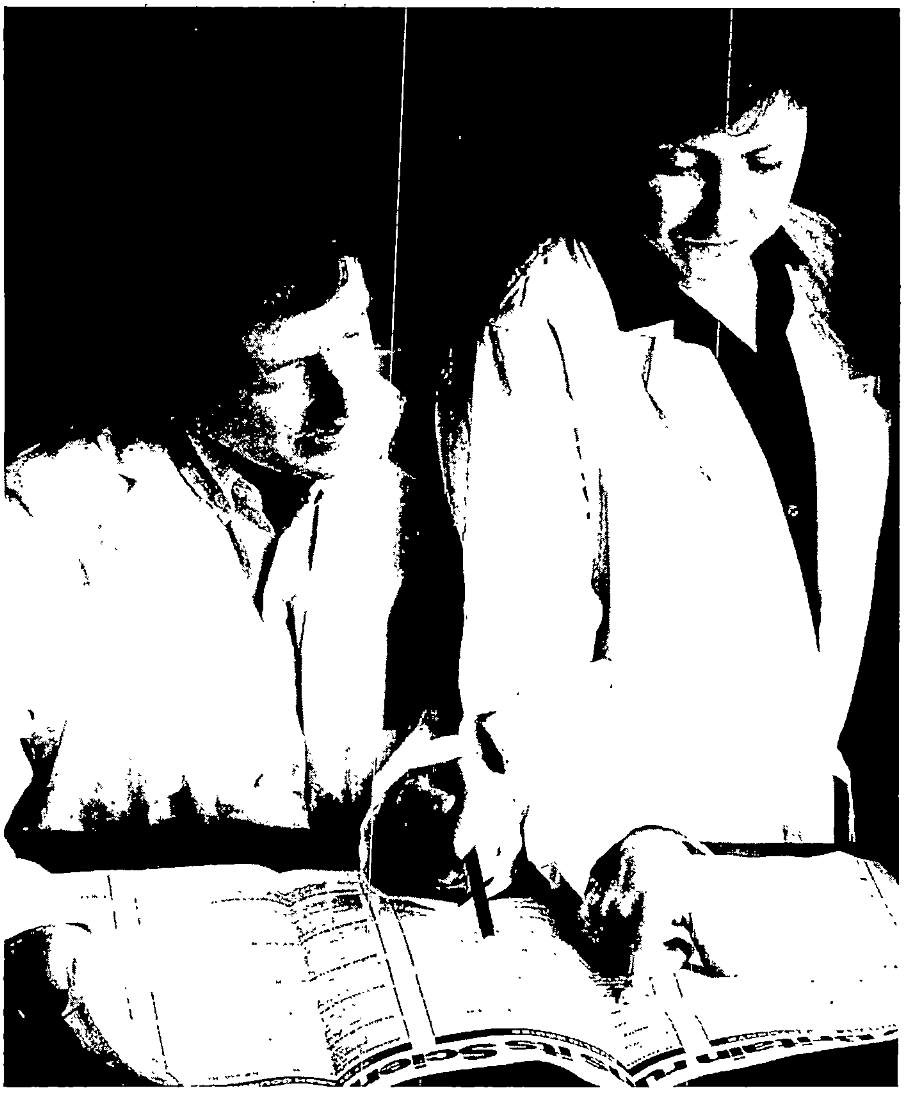
NATURE'S GUIDE TO

HOW BRITAIN RUNS ITS SCIENCE



This highly successful wallchart has now been redesigned and updated to take account of changes in structure and personnel since the previous edition was published in 1983.

Compiled in Nature's editorial office, the guide provides a comprehensive survey of the administration of British science, showing at a glance the functions, key personnel and finance of government departments, public and independent bodies and the research councils.

Designed as a fold-out sheet, in red, blue, black and white, the 60 × 90cm chart can be carried easily to meetings or hung as a wall poster for permanent reference.

Copies are available from: Nature, Brunel Road, Houndmills, Basingstoke, Hants, RG21 2XS, UK. Prices: (including postage and packing) £4.75 (UK), US$8.50 (USA and Canada), £5.75 (all other countries).

Newtonian gravitation corrected

Suspicions that the inverse square law for the gravitational force between two objects may be incorrect at short distances appear to have been confirmed. Better measurements are required.

NEWTON's inverse square law of gravitation may, after all, be incorrect. That is the strange and somewhat mystifying conclusion of the latest investigation of the value of the universal constant of gravitation (G). For although there have been many recent suggestions, theoretical and otherwise, that the strength of the gravitational coupling between massive objects may be a function of distance at small distances, the surprise is that it has now been established by a re-examination of the results of the Eötvös measurements, widely accepted for more than half a century as a proof that gravitational interactions depend only on the mass of the objects involved.

The new development (*Phys. Rev. Lett.* **56**, 3; 1986) is the work of Ephraim Fischbach of the University of Washington, St Louis, Daniel Sudarsky, Aaron Szafer and Carrick Talmadge of Purdue University and S.H. Aranson of the Brookhaven National Laboratory. The essence of their conclusion is that G, the 'constant' in Newton's inverse square law, is in reality a function of the distance separating interacting masses, and is less by a few parts in a thousand at distances of the order of 200 m.

The reasons why G may not be constant have been widely canvassed, and follow naturally from the now common assumption that the four natural forces (gravitation, electromagnetism, the weak and the strong nuclear interaction) are, at some level of abstraction, aspects of one general interaction. Field theorists who have set their sights on the 'grand unification' of the elementary forces have long anticipated this conclusion. In such a scheme, the gravitational interaction between two masses is mostly explained by the exchange of hypothetical field particles ('gravitons'), just as the electromagnetic interaction is accounted for by the exchange of photons between interacting electric charges, but grand unification allows other field particles to chip in, modifying Newton's inverse square law.

The expectations have been nicely put by G.W. Gibbons and B.F. Whiting (*Nature* **291**, 636; 1981) for example, who argued for departures from Newton's inverse square law represented by a G which is a function of the distance r between interacting masses with the form $G = G_o\ (1 + \alpha e^{-r/\lambda})$ where G_o is the value of G at large distances; α and λ are constants, the second of which is determined by the mass of the extra field particle mediating the gravitational interaction and provides a scale of lengths at which departures from the inverse square law should be apparent.

Geophysical data provide supporting evidence. If G varies with distance, and if the characteristic length scale is of the order of metres, the acceleration of a satellite in orbit about the Earth should differ from that expected from the measured acceleration of a mass near the surface of the Earth and from a direct measurement of the force between two masses separated by a few centimetres, as in the measurements of Cavendish a century ago.

Geophysics should yield information on departures from Newton's law a little more directly, as F.D. Stacey and G.J. Tuck have clearly argued (*Nature* **292**, 230; 1981). They showed that it should be possible to use measurements of gravitational acceleration ('little g') in boreholes in the Earth's crust, together with measurements of the density of the rock strata they traverse, to estimate the possibility that G varies with distance. Two years ago (S.C. Holding and C.J. Tuck, *Nature* **307**, 714; 1984), results of gravity measurements in two mineshafts at the Mount Isa mine in Australia were held to be consistent with a variable G, although everybody seems to agree that measurements in mineshafts, especially in metalliferous regions, are far from ideal. Stacey seems to have been the first to press for measurements of g as a function of depth in the deep oceans, where inhomogeneity and uncertainty about the density of the surrounding material would be less serious complications.

Fischbach *et al.* take a different tack, going back to the classical measurements in which Eötvös sought to demonstrate that the gravitational attraction between two objects is simply a function of the product of their masses (and the distance between them). Several pairs of different materials were evaluated against each other — water, copper sulphate, platinum and even tallow against copper, for example. Fischbach *et al.* rightly say that the measurements have been taken as a proof that the mass, and not its constitution, is all that matters.

Their own starting point is more complicated. What if departures from newtonian gravitation are brought about by the exchange of massive photons such as might be associated with the non-conservation of charge and parity (*CP*-non-conservation, as it was called by Lee and Yang in the 1950s)? Then the extra force should be repulsive, and should be determined not by the masses of the gravitationally interacting objects but by their baryon numbers (or, more accurately, by their hypercharges).

But surely the baryon number of one gram of platinum will be the same as the baryon number of a gram of copper sulphate, and simply determined by the number of nucleons it contains? This is the simple explanation. But allowing both for the contribution of electron masses to the total mass of a material, and for nuclear packing fractions, it turns out that there are more baryons per unit mass in the middle of the periodic table (around Fe) than at either end.

All this is beyond dispute. The surprise is that Fischbach *et al.* have been able to find in the original Eötvös measurements evidence of departures from newtonian behaviour that correlate strikingly with the specific baryon number (the number of baryons per unit mass). Naturally, they go on to plead that the experiments should be repeated, but they also go on to say that their conclusion is sustained by measurements of anomalous properties of K mesons (kaons) at high energy.

What is to be made of the conclusion? The claim in the *New York Times* last week that Fischbach *et al.* have discovered a 'fifth force' is a little strong; if there are measurable departures from newtonian gravitation, those described are much what would be expected. That there is a significant difference between laboratory and geophysical measures of G seems now also well attested. The fact that the scale length calculated for the departure from the inverse square law is of the order of 200 m is consistent with that, but should suggest many novel ways of designing critical tests of the gravitational law now put forward.

That, in the end, is how the matter will have to be settled, for it is unthinkable that such an important issue as the behaviour of newtonian gravitation at short distances could for long be allowed to rest on a series of experiments carried out more than 60 years ago. But Fischbach *et al.* have provided an incentive for the design of better measurements by showing what kind of irregularity it will be sensible to look for.

Space physics

Does Uranus have a magnetic field?

from A.J. Dessler

In just a matter of days, Voyager 2, now nearly 8.4 years into its grand tour of the Solar System, will sweep past Uranus. The prospect has inspired discussion of the strength of the planet's magnetic field, published estimates of which at cloudtop level range from tens of gauss down to zero. This fascinating state of confusion is the result of recent data from Voyager which do not confirm past observations of Uranus from Earth orbit.

In 1982, John Clarke, using the Earth-orbiting International Ultraviolet Explorer (IUE), reported that Uranus is a bright scource of ultraviolet light[1]. Clarke's interpretation of these observations, which was immediately and widely accepted, was that the ultraviolet emission from Uranus is radiating from a bright aurora, which would be caused by the bombardment of the upper atmosphere by energetic electrons or ions. It is these and subsequent IUE observations, plus the specific hypothesis of an aurora on Uranus, that led to the estimates of a strong planetary field. To extract power either from the solar wind or from the rotation of the planet so as to drive an aurora that can produce the observed 10^{10} watts of ultraviolet emission, the planetary magnetic field has to create a magnetosphere large enough to engage the power source. Because of our experience with aurora on Earth, Jupiter and Saturn, quantitative models are at hand. Application of these models to Uranus results in a most probable value of the magnetic field at cloudtop level of 4–13 gauss, with 0.6 gauss as the minimum value[2].

Until a few months ago, Uranus was, in a sense, an astrophysical object. It can be seen well enough from Earth (and from Earth orbit) to learn a few facts and to develop some nice stories. Because there are few facts, simple ideas tend to fit them and they become a consensus rather quickly. Uncertainty and debate have been rare. But we are now witnessing a transition of Uranus from an astrophysical object to a space-physics object; facts provided by Voyager are about to overwhelm the theories. The impending encounter has made the theoretical community both humble and open-minded.

The problem is that if the IUE-detected ultraviolet light is indeed from an aurora created inside an enormous magnetosphere, then our experience with Earth, Jupiter and Saturn would lead us to expect Uranus to be a significant source of radio noise. Consequently, it was predicted that Voyager's first detection of magnetospheric radio emission would occur early last year and no later than August[2,3]. The failure of Voyager to pick up any radio signals from Uranus so far suggests that the ultraviolet emission is not generated by an aurora and that a strong (or even a weak) planetary magnetic field may not exist. Alternative explanations for the ultraviolet emission are therefore being put forward.

Shemansky, in the January issue of *Geophysical Research Letters*, and Ip, in next week's *Nature*, agree that the mysterious mechanism that produces bright ultraviolet glow from the sunlit hemispheres of Jupiter and Saturn also operates at Uranus. This glow is not auroral in nature — it occurs at lower and mid-latitudes, stops suddenly in the absence of sunlight and is clearly a separate phenomenon from the standard high-altitude aurora. Shemansky further suggests that Uranus has a negligible planetary magnetic field, while Ip argues that the strength of the magnetic field is immaterial, but it could be quite weak.

The lack of the expected radio emission has inspired yet another argument for a weak magnetic field. Curtis and Mess[4] note that the blackness of the rings and satellites of Uranus could be explained if there were no magnetosphere to shield them from the solar wind. Particle bombardment by the solar wind would remove surface ices, leaving dark, possibly carbonaceous, materials on the surface. They propose a cloudtop magnetic field of no more than 4×10^{-5} gauss.

Another proposal for a weak field will be put forward by Axford and Vasyliunas in next week's *Nature*. They argue that the magnetic field of Uranus originates in an

---

Jacques Oudin 1908–1985

With the death of Jacques Oudin on 15 October 1985, the international community of immunologists has lost one of its uncontested pioneers. From 1937, after completing his medical studies, Oudin spent his entire scientific career at the Pasteur Institute in Paris. From 1959 onwards he headed the laboratory of Immunochimie Analytique which was especially created for him. In 1979, the year after his retirement, a symposium at the Pasteur celebrated his exceptional career, highlighted by three major discoveries.

Some time after joining the Pasteur, while working in the laboratory of Chimie Microbienne, Jacques Oudin attempted to devise a one-step method to count the diverse antigen–antibody systems involved in the reaction of an appropriate antiserum and a complex mixture of antigens. He came up with the remarkable idea of using a gelled medium for the antigen–antibody precipitation reaction designing, in 1946, the method of immunochemical analysis. For a long time thereafter this was the only method for the enumeration and identification of antigens as well as the quantification of antigens and antibodies. Oudin formulated the quantitative laws and the general rules of the method, one of them — for which he had so often to fight — being that an antigen molecule gives only one precipitation zone with the corresponding antibodies.

It was while using antigen–antibody precipitates as immunizing material to elicit production of antibodies unispecific to the antigen present in the complex, that Jacques Oudin observed the first manifestation of what he defined in 1956 as allotypy of proteins, namely their property of exhibiting variations of antigenic specificities among individuals of an animal species. Before the multichain structure of immunoglobulins was known, he showed the presence on the same rabbit immunoglobulin molecule of allotypic specificities governed by genes at two different and independent loci, which he had just identified. The discovery of allotypy opened the fertile field of immunogenetics and the fascinating area of immune-system manipulations.

Working along the same lines, Oudin found in 1963 that rabbit antibodies possessed additional antigenic specificities which seemed unique to antibodies to a given antigen in one individual or a group of individuals. He proposed the term idiotypy to designate them. This observation (made independently in 1963 for human antibodies by Kunkel, Mannik and Williams at the Rockfeller Institute) led to experiments which were crucial to our appreciation of both the potential repertoire of antibody diversity and the regulation of its expression. It also provided the basic material for Jerne's theory of the network of antibody variable-domain interactions and of the dynamic equilibrium of the immune system.

It is worth pointing out how far and wide the words coined by Oudin have spread: isotypy and isotype, allotypy and allotype, and particularly idiotypy and idiotype. But it would be presumptuous to try to capture with mere words the rigour of Jacques Oudin's scientific thinking, the peculiarity of his solitary creativeness, his talent in identifying important facts in unexpected findings that would have disconcerted less discerning minds, his intransigent empiricism, his perfectionism and the extreme care he took over all his writing. We have been priviledged to benefit from such an exemplary mind.

Guy Bordenave

Earth-sized core, and they assume that the magnetic field from a body of this size must be about the same as the Earth's at the surface of the core. Thus, they conclude that the magnetic-field strength at cloudtop levels is about 10^{-2} gauss.

The proponents of a strong cloudtop magnetic field ($\geqslant 0.6$ gauss) for Uranus have become quiet apologists for the radio noise that has not been detected by Voyager: the radio emissions might be beamed away from the spacecraft; the aural electrons may be too low in energy (<1 keV) to support the excitation of radio emissions; there may not be enough background thermal plasma for the auroral beams to become unstable to radiofrequency oscillations; the magnetic field of Uranus may be so strong that the radio emissions are above the sensitive range of the Voyager radio receivers; the magnetosphere may be rather quiescent so that energetic particles that lose their energy through synchrotron radiation are not quickly replaced; and so forth.

Vociferous arguments in either side are lacking. The reason is plain — some of us are going to be embarrassed. Also, we have learned from other planetary encounters that nature is so clever at putting things together in completely unexpected ways that we now almost count on being astounded by what we find.

One cannot but wonder how, in a distant future, a community of, say, pulsar theorists will behave when an interstellar probe is about to fly by a pulsar for the first time. Rotating neutron star indeed! ☐

Earth sciences

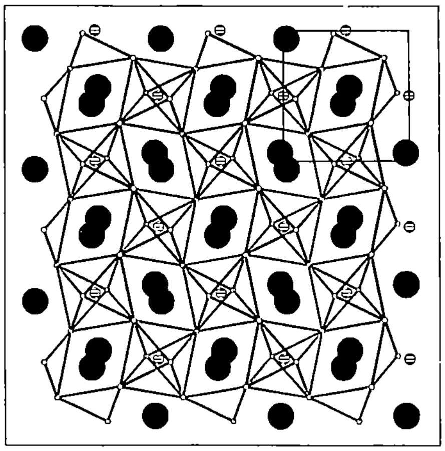
Perovskites and plate tectonics

from Geoffrey D. Price

OUR ignorance of the dynamics of the Earth's mantle is such that it is still considered debatable whether the mantle convects as a whole, or in layers, divided one from another by a phase change or chemical boundary at the 670-km seismic discontinuity that separates the upper and lower mantle. Even though magnesium silicate perovskite probably makes up the vast majority of the lower mantle, and perhaps up to 40 per cent by volume of the entire Earth, little is known about its phase relations, its flow characteristics or its physical properties, all of which will critically influence the rheology and convective behaviour of the mantle. It is therefore essential to have a full knowledge of the nature of silicate perovskites if we are to understand the thermomechanical and chemical evolution of the Earth. The paper by Knittle *et al.* on page 214 of this issue attempts to provide the first data needed to begin such a task.

The lack of data on silicate perovskites is quite understandable, as it is not yet technically possible to measure the structural and physical properties of materials at the high pressures (>200,000 atm) and temperatures (>2,000 K) thought to characterize the lower mantle. To date, therefore, most of the theories concerning the behaviour of mantle-forming perovskite have have been derived from the study of the behaviour of non-silicate perovsites. For example, O'Keeffe and Bovin (*Science* **206**, 599; 1979) as well as Poirier *et al.* (*Phys. Earth planet. Inter.* **32**, 273; 1983) have suggested that magnesium silicate perovskite may behave like $NaMgF_3$ or $KZnF_3$, which are solid electrolytes at high temperatures.

Until now, work on magnesium silicate perovskite itself has been confined to its synthesis, its structure determination and the study of its phase relations in the $MgO{-}FeO{-}SiO_2$ system. The study of the thermal expansion of magnesium silicate perovskite by Knittle *et al.* is therefore to be welcomed as the first direct determination of any physical property of this mineral, and assumes particular significance when it is realized how difficult it is to use the diamond anvil cell to synthesize the quantity of perovskite that was needed for the thermal expansion study. Such cells are notorious for producing impurities, because of the heterogeneous nature of the pressure and temperature distribution within the cell, but Knittle *et al.* have obviously overcome these problems to the extent that they have produced material which behaves in a systematic and reproducible fashion.



A polyhedral projection of the orthorhombically distorted perovskite structure adopted by magnesium silicate perovskite under ambient conditions. Magnesium ions (large filled circles) sit in the distorted cages formed by the outlined corner-sharing SiO_6 octahedra.

Because of the metastability of magnesium silicate perovskite under ambient pressure conditions, when studying its thermal expansion behaviour Knittle *et al* were restricted to temperatures below 840 K. To address questions concerning mantle processes, they were therefore forced to extrapolate from their data to the pressures and temperatures found in the lower mantle. They are on relatively firm ground in doing this when discussing the variation in the physical properties of perovskites with changing environment. But, unfortunately, crystal chemical models are less robust to extrapolation than are equations of state, and consequently their conclusions concerning the possible changes in the structure of perovskite with increasing depth within the mantle are conjectural in the extreme. Silicate perovskites develop an orthorhombic distortion (see figure) under ambient conditions, but the nature of possible changes in the perovskite structure at high pressures and temperatures has excited considerable debate (for example, O'Keeffe, M. *et al. Phys. Chem. Minerals* **4**, 299; 1979), and Knittle *et al.* cannot really shed light on this aspect of perovskite behaviour.

From their analysis of the thermal expansion behaviour of silicate perovskite, Knittle *et al.* infer that the lower mantle must be enriched in iron or silica relative to the upper mantle, and reasonably conclude that the upper and lower mantle must convect separately, and that mantle-wide chemical mixing is impeded. The experimental difficulties involved in studying these high-density silicates are such, however, that the uncertainty in their measurements are large: indeed the results are compatible with perovskite thermal expansion coefficents that range from 2×10^{-5} to 6×10^{-5} K^{-1}. Although not discussed in detail, it is to be expected that such uncertainties are too large to enable the conclusions drawn by Knittle *et al.* to be considered definitive. Nevertheless, their approach must be pursued, as it will only be from such investigations that we will be able to determine the true nature of mantle behaviour and thereby understand the fundamental processes involved in plate tectonics and the evolution of the Earth. ☐

Geoffrey D. Price is a Royal Society 1983 University Research Fellow in the Department of Geological Sciences, University College London, London WC1E 6BT, UK.

Inositol phosphates

Profusion and confusion

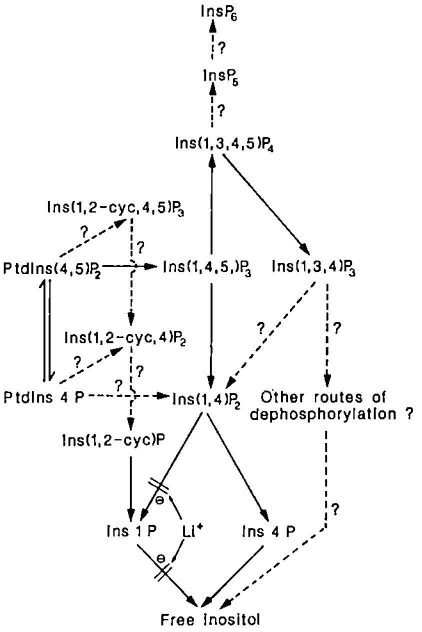
from Bob Michell

AFTER many years of argument, the past two years have brought agreement that receptor-stimulated hydrolysis of inositol phospholipids is a common mechanism for transmembrane signalling when cells respond to external stimuli such as hormones, neurotransmitters, antigens, light and some growth factors (reviewed in refs 1–3). But just as a slide depicting the simultaneous formation of two 'second messengers' within the cell by hydrolysis of phosphatidylinositol 4,5-bisphosphate (PtdIns(4,5)P_2) seems to have become a standard part of the travelling baggage of any scientist with an appreciable interest in cell responses to external stimuli, results from several laboratories suggest that this picture is greatly oversimplified. An up-to-date version of the formation and metabolism of inositol polyphosphate 'messengers' would need, unfortunately, to look something like that shown here.

The second messengers produced by the phosphoinositidase C (PIC)-catalysed hydrolysis of PtdIns(4,5)P_2 are *sn*-1,2-diacylglycerol and D-inositol-1,4,5-trisphosphate (Ins(1,4,5)P_3). The latter exerts its intracellular actions by releasing Ca^{2+} from an intracellular store, maybe in a compartment of the endoplasmic reticulum that is close to the plasma membrane[2], through interaction with an 'IP_3 receptor' that has now been detected by direct binding studies using liver microsomal membranes[4]. In solution at neutral *p*H, Ins(1,4,5)P_3 adopts the 'chair' configuration, with three phosphate groups lying around the periphery of the inositol ring[5], and this may be the configuration recognized by its receptor. The major mechanism for terminating Ins(1,4,5)P_3 action is thought to be removal of the 5-phosphate by a family of specific phosphatases, present both in the plasma membranes and cytosol of stimulated cells. Although this picture of the formation, second messenger action and inactivation of the released inositol trisphosphate headgroup is almost certainly correct, it is now clear that several additional inositol polyphosphates, with as yet unknown functions, are produced in stimulated cells.

The first hint of this unexpected complexity came last year when Robin Irvine and Peter Downes discovered that much of the $InsP_3$ that accumulates in cholinergically stimulated parotid glands is the 1,3,4-isomer rather than the expected 1,4,5-isomer[6]; although the Ins(1,4,5)P_3 formation is immediate, that of the Ins(1,3,4)P_3 is delayed as is its decline on removal of the stimulus[7,8]. The origin of Ins(1,3,4)P_3 was a mystery until the recent evidence for its formation by dephosphorylation at the 5-position of D-inositol 1,3,4,5-tetrakisphosphate (Ins(1,3,4,5)P_4)[11], probably by what had been characterized as an Ins(1,4,5)$P_3$5-phosphatase[9,10].

Ins(1,3,4,5)P_4 is formed as rapidly as Ins(1,4,5)P_3 in various stimulated tissues and cells[11,12] and at a recent meeting on inositol lipids in Germany*, Irvine and Michael Berridge presented evidence for a novel ATP-dependent kinase that converts Ins(1,4,5)P_3 to Ins(1,3,4,5)P_4. Because the absolute rates of synthesis and degradation of Ins(1,4,5)P_3 and of Ins(1,3,4)P_3 in stimulated cells appear to be of the same order, at least in the parotid gland[7], the pathway for metabolism of Ins(1,4,5)P_3 through Ins(1,3,4,5)P_4 to Ins(1,3,4)P_3, and hence for its inactivation as a Ca^{2+}-mobilizing ligand, may be quantitatively as important as its dephosphorylation to Ins(1,4)P_2. Although it seems quite likely that Ins(1,3,4)P_3 and/or Ins(1,3,4,5)P_4 will turn out to have intracellular messenger functions of their own, this idea remains to be tested because so far the compounds have only been obtained in trace quantities.



Some known (→) and probable ($\overset{?}{\dashrightarrow}$) interconversions of inositol lipids and inositol phosphates in stimulated cells.

Having found these unexpected inositol polyphosphates, the Cambridge groups looked further, and found that GH4 cells contain both an inositol pentaphosphate ($InsP_5$) and an inositol hexaphosphate ($InsP_6$), although their concentrations do not change dramatically on stimulation of cells[12]. There seem to be no previous reports of such highly phosphorylated inositol derivatives in mammalian cells, and their function and metabolism are unknown. However, $InsP_6$, better known as phytate, is a major phosphate store in some seeds, and the 1,3,4,5,6-isomer of $InsP_5$ is an allosteric regulator of oxygen binding to haemoglobin in avian erythrocytes.

Almost 15 years ago, it was discovered that a major product of PIC hydrolysis of phosphatidylinositol in cytosolic and plasma membrane fractions from brain is inositol 1,2-cyclic monophosphate[13–15] and that there is a widespread and specific phosphodiesterase that opens the 1,2-cyclic phosphate ring of this compound at the 2-position[16,17]. As a result, inositol 1,2-cyclic phosphate was briefly considered as a possible intracellular messenger compound[15]. Philip Majerus and his colleagues in St Louis have now found that 1,2-cyclic derivatives can also be produced from PtdIns(4,5)P_2 and PtdIns4P by two PICs isolated from sheep seminal vesicles, although in smaller quantities than the non-cyclic alternatives[18,19]. D-inositol-(1,2-cyc,4,5)trisphosphate (Ins(1,2-cyc,4,5)P_3) is less potent than Ins(1,4,5)P_3 in mobilizing Ca^{2+} in permeabilized platelets but more so in depolarizing intact *Limulus* photoreceptors[19]. Although these observations show that Ins(1,2-cyc,4,5)P_3 can mobilize Ca^{2+}, we do not yet know whether it is among the products of receptor-stimulated PIC activity in stimulated cells, because it would not survive the acidity of the media that are used for the efficient extraction of inositol trisphosphates from stimulated cells. If the 1,2-cyclic derivatives are formed in stimulated cells, it seems likely that they will be degraded, albeit more slowly, by the phosphatases that degrade Ins(1,4,5)P_3 and Ins(1,4)P_2, with the 1,2-cyclic ring being opened only after dephosphorylation to inositol 1,2-cyclic monophosphate[20]. Ins(1,2-cyc,4,5)P_3 may also be a substrate for Ins(1,4,5)P_3 3-kinase, so giving rise to Ins(1,2-cyc,3,4,5)P_4 and other cyclic phosphates derived therefrom.

A feature of the metabolism of receptor-generated inositol phosphates that has caused particular interest is its inhibition by Li^+ ions at extracellular concentrations similar to those that are effective in suppressing manic depressive symptoms. The dominant idea is that Li^+ inhibits Ins1p phosphatase[21] and thus may limit the supply of free inositol for inositol lipid synthesis (see ref. 2) and limit a cell's signalling capacity. Recent studies both *in vivo*[22] and *in vitro*[23,24] have, however, shown that Ins(1,4)P_2 can be degraded to inositol via inositol 4-phosphate as well as via inositol 1-phosphate. At least in liver, degradation via the 4-phosphate is Li^+-insensitive, whereas both steps in degradation via inositol 1-phosphate are equally Li^+-sensitive[24]. The relative rates of Ins(1,4)P_2 degradation by these two routes are not known for any intact cells, but it seems probable that variations in this ratio will render signalling more sensitive to Li^+ in some cells than in others.

---

*Inositol lipids and signal transduction, the 4th Ernst Klenk Foundation Conference, was held in Koln, FRG on 27–30 October 1985.

The point that emerges particularly forcefully from all of these recent findings is that the metabolism of inositol phosphates in stimulated cells is startlingly complex. It is clear that the very simple anion-exchange chromatographic methods that have been widely used for separating various inositol phosphate 'fractions' in recent years are quite unsuitable for analysing the complex mixtures of inositol phosphates present in stimulated cells. At present, the preferred method for more stringent analyses of the inositol metabolites present in stimulated cells is undoubtedly high-pressure liquid chromatography on anion-exchange resins. Three published methods[7,19,25] each have some desirable features, but we can look forward to refinement of such methods and to the development of selective and sensitive assays for individual inositol phosphates. ☐

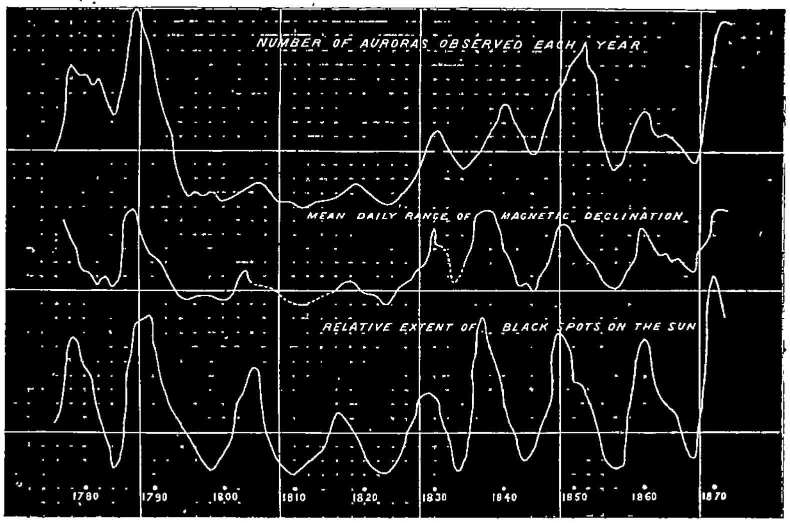
SOLAR SPOTS, MAGNETIC DECLINATION, AND AURORAL DISPLAYS.



Materials science

Limits to Coulomb's law

from Robert W. Cahn

MANY of the scientific laws that the readers of this journal absorbed in their youth are more than a century old and a surprising number go back more than two centuries — but which of them can still claim exact congruence with experimental facts? Some continue in daily use as sound approximations, for example, Boyle's, Hooke's and Ohm's laws, but lose their applicability in specific contexts, such as the behaviour of supercritical steam, 'potty putty' or semiconductor resistivity. Others, such as Newton's laws of motion, remain very close approximations to the behaviour of the real world until extreme conditions (for example, velocities) are attained. On page 203 of this issue, K. Kendall challenges another venerable law — Coulomb's law, formulated in 1773, which describes the frictional behaviour of a bed of power.

According to Coulomb's law, the frictional force between a particle and a smooth plane pressed together by a normal force w is expressed as $f = k + \mu w$, where μ is the friction coefficient and k is a constant representing the intrinsic interaction — the van der Waals' attraction — between the mating surfaces. Coulomb's law has been used for a long time in engineering calculations, particularly in soil mechanics. Kendall now reports on experiments with wet sand confined between two silica plates and finds that the friction coefficient varies substantially, both with normal load and particle size.

The new findings imply that the van der Waals' interaction between, for example, two equal spheres depends on their diameters and on the force pressing them together; this was first established by K.L. Johnson, K. Kendall and A.D. Roberts (*Proc. R. Soc.* **A324**, 301; 1971). If other factors are constant, the friction in a powder bed will rise rapidly as finer particles are used. In view of the widespread use of ultrafine powders in advanced ceramics, this finding has considerable practical importance. As with other named laws, Coulomb's law will presumably remain an adequate approximation under the normal circumstances of coarse powders and soil mechanics, but not under extreme conditions.

Coulomb's law is just one small feature of the varied, untidy but widely useful field of powder mechanics, a term not commonly used, but one that collectively covers dynamics, statics and thermodynamics. Consider some of the ways a powder can behave. When dry and in a still atmosphere, a powder has a 'flowability' that depends on particle mean size, size distribution, mean shape and shape distribution and on intrinsic frictional properties. An assembly of needles may stick obstinately, whereas dry uniformly-sized sand flows easily. The capillary effect of moisture is crucial: common salt needs a hygroscopic additive to keep it free-running; dry powder snow responds to pressure quite differently from wet snow, as any skier knows. If the proportion of water becomes too high, the result may be an avalanche or a quicksand.

A dry powder can be made fluid by blowing air or some other gas through it. Such a 'fluidized' bed has much lower friction than a normal powder bed and resembles a highly mobile liquid. The theory of fluidized bed mechanics and heat transfer is important in chemical engineering, because such beds are commonly used for reacting solids with hot gases. When the gas pressure becomes too high, the agitation of the powder leads to erosion of the container. Such erosion has implications ranging from particle impact on the windscreens of supersonic aircraft to the sandblasting of castings or spark plugs. The abrasive wear of surfaces by powders has also become a large field of study.

The optimum feasible irregular packing of powders leads to complex statistical issues, which have been treated by J.D. Bernal and J.L. Finney (*Nature* **213**, 1079; 1967 and *Proc. R. Soc.* **A319**, 479; 1970). Their concept of dense random packing of equal-sized spheres, originally conceived as a model for monatomic liquids, has been extremely influential in guiding the modelling of metallic glasses. Surprisingly, a randomly packed assembly of monosized spheres can be within about five per cent of the density of a regular close-packed array. Dense random-packed arrays can be further densified by sintering, a technique that goes back to prehistoric practice in the baking of pottery. The stereology of solid-state sintering — the developing relation between packing fraction, porosity, permeability and specific surface area — has become a major field of scientific enquiry with relevance to metallurgy, ceramics and catalysis, and several novel experimental and conceptual tools have evolved with it. The mechanics of sintering — notably the crucial role of the curvatures of internal free surfaces and of intercrystalline boundaries — are now well understood. Through doping, subtle control of the motion of such boundaries has been achieved, making it possible to sinter to full denstiy; the absence of scattering from pores has enabled the creation of translucent or transparent polycrystalline ceramics, now used in very efficient high-temperature lamps.

The ubiquity of powders in applied science indicates that Kendall's discovery of a major departure from a long-accepted powder law is of wider import than might at first appear. We still have to see how representative the circumstances of Kendall's experiments are. He used a wet load and the moisture fraction is not stated; presumably dry sand would behave quite differently. The plastic domain, as in hot isostatic pressing of metallic powder compacts, must entail frictional regimes quite different from those in the elastic regime treated by Kendall. Even so, his work has reopened a field that has been hemmed in by orthodoxy and neglected because ultrafine powders have only recently become commercially important. ☐

Cosmic rays

Where do antiprotons come from?

from Andrew Buffington

IT IS usually believed that the antiprotons ($\bar{p}$) in cosmic rays result from collisions between high-energy protons (p) and ambient interstellar gas. Recent measurements of $\bar{p}$ cosmic-ray fluxes between 0.1 and 10 GeV are, however, inconsistent with such a secondary source, if the observed p fluxes are assumed to illuminate the 5 – 7 gm cm^{-2} of interstellar material that has been deduced from studying heavier cosmic rays. Moreover, there is a kinematic cutoff for the reaction threshold of interstellar gas 'target-at-rest' interactions that predicts a dramatic drop in the $\bar{p}/p$ ratio below a few GeV, but the measurements show a practically constant ratio of 3×10^{-4}. The discrepancy factor at higher energy is about 5 but grows to about 100 close to 0.1 GeV. On page 205 of this issue C.D. Dermer and R. Ramaty[1] cite the recent $\bar{p}$ flux measurements and present a possible explanation for the reported similarity in $\bar{p}$ and p spectra.

Dermer and Ramaty suggest that the target material that is illuminated by high energy p to produce the $\bar{p}$ could be a relativistic plasma instead of cool interstellar gas. Such a plasma might be found in the vicinity of neutron stars or black holes. They then calculate that target particle motion is sufficient to remove most of the suppression of low energy $\bar{p}$ and show that production rate is significant for plasma temperatures above about 0.2 M_pc^2. They discuss constraints put on the model by γ-ray measurements and suggest that many of the observed antiprotons were originally created as antineutrons, whose charge neutrality helped them to escape confinement in the ambient plasma magnetic field.

Many authors have already advanced a variety of explanations for the $\bar{p}$ anomaly with models that range from those invoking primary antimatter to those that adopt closed-galaxy cosmic-ray propagation or various types of shells around some of the cosmic-ray sources. Some of these are cited by Dermer and Ramaty, to which might be added an important calculation of secondary $\bar{p}$ production by Protheroe[2], models by Kiraly *et al.*[3], Eichler[4], and Lagage and Cesarsky[5], and neutron oscillation as a possible separate source of low energy $\bar{p}$[6,7]. I consider that the recent $\bar{p}$ flux measurements have stimulated significantly revised calculations of $\bar{p}$ production in thick targets. In these, the effect of further $\bar{p}$ collisions has been included, particularly because these can 'fill in' the kinematic suppression of the $\bar{p}/p$ ratio at low energy. Tau and Ng[8] and Protheroe[2] have shown that the observed $\bar{p}$ spectrum can be matched, provided the $\bar{p}$ were produced in material with a thickness of about 30 gm cm^{-2}. In the case where all the $\bar{p}$ are secondary, the question becomes where might reside such a thickness for cosmic-ray protons to pass through and to what extent the heavier cosmic rays may also have passed through it. If the $\bar{p}$ are considered as secondary, our understanding of galactic cosmic rays stands at a major crossroads because $\bar{p}$ provide a unique tracer for the interactions of the primary p. (The spectrum of positrons, the other possible interaction-daughter candidate, are altered too much by photon interactions subsequent to their production to be useful.) The question is: should we adopt a different history for the plentiful cosmic-ray p, compared with that for the heavy cosmic rays?

We do not at present know what measurements could provide a definitive answer to this question but helium isotope spectra may be important as the next step. Because the helium-interaction mean free path is comparable to the 30 gm cm^{-2} of material indicated for parent-proton cosmic rays, considerable helium should survive the passage through even this thickness of material. As ^{3}He is expected to be rare in the cosmic-ray sources, the ^{3}He/^{4}He ratio shows whether helium cosmic rays have passed through a large amount of material, as some of the above models would predict. Recently, Jordan and Meyer[9] reported the first measurement of ^{3}He/^{4}He near 6 GeV per nucleon, an energy high enough that little correction is needed for solar modulation. They report a ratio of 0.24, which requires about 15 gm cm^{-2} of interstellar material. On the other hand, measurements of this ratio below a few hundred MeV per nucleon are consistent with the 5 – 7 gm cm^{-2} indicated by heavier cosmic rays, but in an energy range strongly affected by solar modulation. This discrepancy was the subject of lively discussion at a recent conference[10,11], so clearly Jordan and Meyer's result is not yet generally accepted.

These experiments are technically difficult, so that confirming and expanding experiments have been slow in coming, but this wave of new ideas about cosmic-ray origin and propagation needs new and better data to carry it along. It will be particularly important to have improved $\bar{p}$ data below 2 GeV, where the spectrum carries much information about re-interaction of the secondary $\bar{p}$; confirmation and extension of the high-energy helium isotope data is also needed. The group led by R. Golden at New Mexico State University has reconfigured their magnetic spectrometer, now ready for a new balloon flight, for $\bar{p}$ measurements to a lower energy range than they used previously; they have also made significant improvements in their trajectory measuring apparatus. New $\bar{p}$ instruments are also being planned by Goret[12] and by groups at Berkeley and Goddard[13,14]. Although no high-energy ^{3}He/^{4}He experiments seem to be planned, the stimulating and exciting new results underscore their need. ☐

Marine reptiles

Lifestyle of plesiosaurs

from Michael A. Taylor

THE plesiosaurs, large extinct carnivorous marine reptiles of the Mesozoic period, have always excited dispute over how they swam[1] and reproduced. Did they swim like marine turtles, 'flying' with winglike, hydrofoil limbs, or did they row by moving their limbs back and forth (Fig. 1*a*, *b*)? And did they come on shore to lay eggs, or give birth in the water to live young? Recent research provides a new animal model that might answer these questions.

In 1975, Jane Ann Robinson argued that the plesiosaurs must have flown underwater, like turtles and penguins, because this movement was the most efficient use of their long hydrofoil-like limbs[2]. If the plesiosaurs had rowed, they should have had webbed folding feet like those of ducks. She suggested that they swam by flapping both pairs of limbs up and down, producing lift force that propelled the animal forwards.

Seven years later Samuel Tarsitano and Jürgen Riess suggested a modification to Robinson's analysis[3]. Although agreeing that plesiosaurs must have used their limbs to fly underwater, they noted that the simplest — and apparently most effective — up-and-down action was anatomically impossible because the bones of the shoulder joints would block the appropriate operation of the forelimbs above the horizontal. Moreover, plesiosaurs do not seem to have had the large dorsal muscles needed to lift the wings powerfully upwards. Dino Frey and Jürgen Riess[4] then suggested that the 'wings' had an active downstroke, and a comparatively passive upstroke as they were returned to the starting point. They suggested that the two pairs of limbs beat out of phase: one pair propelling the animal during its downstroke while the other was being brought back to the start of its own active stroke. This limb action would still be relatively inefficient compared with that of modern animals such as penguins, whose wings produce propulsive force throughout virtually the whole of the upstroke and downstroke.

Stephen Godfrey has now suggested a different living model for comparison[5]. The sealion swims by beating its forelimbs forcefully downwards and then relatively passively upwards, while always moving them backwards. Once fully backwards, the limbs can then be feathered and brought forwards during the recovery stroke. Evidence points to the plesiosaurian shoulder and hip girdles having the massive muscles needed for such limb action (Fig. 1c). Ironically, sealion swimming combines elements of underwater flight — up-and-down action — with rowing — backwards movement. The new model thus combines both the old theories

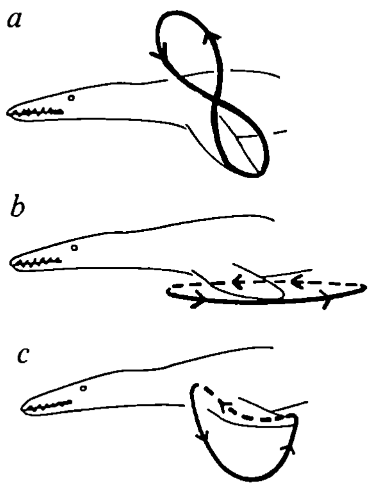

Fig 1. Possible mechanisms for swimming in plesiosaurs. The lines indicate the movement of the wingtip. *a*, Flying underwater like a penguin, with an up-and-down beat of the limbs; this movement would have been ideal for the limb shape but only the downstroke could have been really powerful. *b*, Rowing underwater like a duck, with an active power stroke backwards (bold line) then a recovery stroke forwards (dotted line). The plesiosaur's limb shape is particularly unsuited to such a movement. *c*, Swimming like a sealion, with a backwards power stroke and forwards recovery stroke, a movement combining elements of *a* and *b*.

If the plesiosaur had a swimming movement similar to that of the sealion, with a powerful downwards and backwards thrust, it is slightly easier to imagine how it pushed itself along a beach. However, the plesiosaurs with their rigid bodies could not have humped themselves along as sealions do but must have dragged themselves along, belly to sand, much as sea turtles now do. Whether they also laid eggs in the sand like turtles, or gave birth to live young in the water, as sea snakes do and ichthyosaurs are known to have done, is still unresolved.

The discovery of a pregnant female plesiosaur would settle the question, but none has yet been found. Perhaps we have not looked inside the bodies of enough plesiosaurs or perhaps the embryos decomposed before they could become fossilized. Two early reports of relevant fossils have recently been discounted. In the 1880s H. G. Seeley described an intriguing clutch of diminutive plesiosaur embryos from Whitby, Yorkshire, a discovery forgotten until R. A. Thulborn re-examined it[6]. The find turned out to be a forgery, an unusually shaped nodule (originally, he suggests, shrimp burrows) which had been 'improved' to strengthen resemblance to a clump of plesiosaur embryos, each several inches long. And a reported 'plesiosaur egg'[7] is now thought to be an inorganic concretion[8]; even if it was an egg, it would probably be crocodilian, because crocodiles were much more common than plesiosaurs in the Upper Lias of Whitby.

Tantalizingly, one clutch of eggs — but no young reptiles — was long ago reported from marine beach (or close inshore) deposits from the Middle Jurassic near Cirencester, England[9]. Again these were described as crocodilian rather than belonging to the much rarer plesiosaurs. What is needed, of course, is a clutch of eggs *in situ*, complete with tiny plesiosaurs; but such finds are exceedingly rare even for land animals such as dinosaurs[10] and are even more unlikely to have been preserved on a wave-washed beach. ☐

Neuroendocrinology

Molecular approach appraised

from Stafford Lightman

The mechanisms controlling neuroendocrine regulation can be modulated by a variety of hormones, neurotransmitters and neuromodulators both *in vivo* and *in vitro*. As these systems have been well characterized by physiologists, they clearly offer an extremely attractive model in which to study the control of gene expression. The benefits and problems of the application of molecular genetics to neuroendocrine models were brought up to date at a recent meeting*.

Characterization of the precursors of hormones continues to be an important step in understanding the regulation of hormone production and in the discovery of new candidate hormones. A good example is the recent description of the precursor to gonadotropin-releasing hormone (GnRH) with its carboxy-terminal sequence GAP, which itself inhibits prolactin and stimulates gonadotropin secretion (Nikolics *et al. Nature* **316,** 511; 1985). Further studies (P. Seeburg, Genentech) confirm that GAP coexists with GnRH in hypothalamic cells, but also show that it is present in portal blood and even in the ovary and testis where GnRH has previously been demonstrated.

Except in frog skin, where it is found in abundance (Richter, D. *et al. EMBO J.* **3,** 617; 1984), the precursor to the tripeptide (Gln–His–Pro) releasing hormone, TRH, has been particularly difficult to identify. The problem has now been circumvented with antibodies to a synthetic peptide (Cys–Lys–Arg–Gln–His–Pro–Gly–Lys–Arg–Cys) presumed to represent a portion of the TRH precursor (R. Goodman, New England Medical Center, Boston). The antibodies were used to screen a DNA library from rat hypothalami, which yielded a cDNA clone that encodes a protein containing five copies of the sequence Gln–His–Pro–Gly, flanked by pairs of basic amino acids. In support of the view that this protein is a TRH precursor, *in situ* hybridization with the cDNA was shown to detect neurones in those regions of the hypothalamus that are known to produce TRH. Thus, as with enkephalin, TRH has a precursor from which multiple copies of the biologically active peptide can be produced. Oddly, there is no homology between the frog-skin and rat hypothalamic precursors except for the TRH units themselves.

Defining the mechanisms of gene regulation is a major challenge to the molecular neuroendocrinologist. Quantitation of changes in pro-opiomelanocortin (POMC) mRNA in the anterior pituitary in response to corticotropin releasing factor and dexamethasone, or in the pars intermedia in response to bromocriptine, provide evidence of control at the level of gene transcription (J. Roberts, Columbia University, New York). The situation is more complex, however, in sex-hormone mediated changes in the arcuate nucleus of the hypothalamus. Treatment of a two-week ovariectomized adult rat with oestradiol results in a slow decline in the concentration of POMC mRNA in the arcuate nucleus and the expected corollary, a rapid decline in POMC transcription, which remains suppressed for days.

On the other hand, events controlling dopamine synthesis in the same system are not so clear. Oestradiol administration results within one hour in a fall of the transcription of the gene for tyrosine hydroxylase (TH) — the rate-limiting enzyme in catecholamine synthesis — with a gradual return to normal over 4 days, whereas the amount of TH mRNA begins to increase after 20 minutes and continues to rise for 4 days. This dissociation of the quantity of TH mRNA from the level of transcription of its gene implies that mRNA stabilization may be responsible for some of the quantitative changes in TH mRNA. Clearly, turnover of TH mRNA is the variable that we should like to measure, but the techniques are not available and, in particular, we have no idea how to study the rate of specific mRNA degradation.

Similar problems apply to the interpretation of *in situ* hybridization studies, in which the hybridization of intracellular mRNA with specific DNA probes is used to locate sites of gene expression in tissue sections. This technique cannot provide any measure of RNA turnover and suffers from a lack of sensitivity which still limits its application to quantifying intracellular mRNAs. Nevertheless, it is finding many applications. For example, POMC mRNA can be detected in the pars intermedia of the rat pituitary, but in the anterior pituitary it is only found after adrenalectomy (J. Coghlan, University of Melbourne). Atrial natriuretic peptide mRNA could not be detected in the hypothalamus but has been found in the cardiac atria; renin mRNA has been detected for the first time in the arcuate nucleus. Vasopressin and oxytocin cDNA probes have now been used to measure mRNA responses to different physiological conditions (J. McCabe, Rockefeller University). Rats whose drinking water has been substituted with two per cent saline have an increased proportion of hypothalamic magnocellular cells heavily labelled by vasopressin cDNA, and magnocellular cells from 15-day pregnant rats show an increase both in the number of heavily labelled cells and in the number of cells with any autoradiographic grains. Further experiments are needed to show whether this represents two different groups of responding cells within the magnocellular paraventricular nucleus.

Novel techniques to measure gene expression and post-translational processing are exciting considerable attention. One method of incorporating mRNA into cells is by the use of a vaccinia virus (VV) vector (G. Thomas, Oregon Health Sciences University). The infection cycle of VV, unlike that of other DNA viruses, occurs solely in the cytoplasm of the host cell. Insertion of a cDNA downstream from an early VV promoter leads to transcription of the cDNA in the host cell within minutes of infection and to efficient production of protein from the mRNA. The potential of the technique is illustrated by the infection of different cell lines with recombinant VV containing the cDNA for human proenkephalin. Infected BSC-40 cells contain 2 main peaks of enkephalin immunoreactivity of which only the larger precursor is secreted into the medium. Infected AtT-20 cells, however, contain five peaks of immunoreactivity, with met-enkephalin as the major secreted form. This is a good example of tissue-specific processing. The considerable versatility of the VV system will doubtless provide much further information on this and other processing systems. ☐

Carbon cycle

Photosynthesis seen from above

from R.A. Warrick

ONE of the latest developments in remote sensing, reported by Tucker *et al.* on page 195 of this issue[1], is the capacity to estimate green-leaf biomass of plant canopies and, presumably, terrestrial photosynthesis and primary production, on a global scale with fine temporal and spatial resolution. This development has the potential to sharpen our understanding of the role of terrestrial biota in the carbon cycle and could allow the monitoring of important changes in global vegetation and productivity resulting from increasing atmospheric CO_2 and climatic changes.

As a result of fossil fuel burning, deforestation and other changes in land use, the atmospheric concentrations of CO_2 have risen from a pre-industrial (mid-nineteenth century) level of 275±10 to 343±1 parts per million by volume in 1984 (ref. 2). With a doubling of the pre-industrial CO_2 level the world could become considerably warmer, by 1.5–5.5°C according to climate modellers[3] — the much-debated greenhouse effect. A major issue is when will this happen. The answer depends largely on future rates of energy consumption and CO_2 emissions, together with the sources and sinks of CO_2 and the fluxes between the various carbon reservoirs, which are the subjects of global carbon-cycle modelling. The terrestrial biota is a major component of such models.

In the presence of light, atmospheric CO_2 is assimilated by plants and transformed into carbohydrates — the process of primary production. Through respiration and the decay of organic matter, CO_2 is released back into the atmosphere. Because the rates of assimilation and release are dependent on solar radiation and temperature, and because the distribution of the terrestrial biota is lop-sided in favour of the northern hemisphere, the atmospheric CO_2 concentration has a strong seasonal cycle whose amplitude varies spatially. It has long been suspected that global-scale CO_2 variations are due to variations in primary production of the terrestrial biota, but the empirical demonstration and quantification of this has been hindered by insufficient data coverage, in terms of both time and space.

The remote-sensing techniques discussed by Tucker and his colleagues[1] take a large step towards remedying this problem. Their method involves advanced very high-resolution radiometer (AVHRR) sensors carried by the National Oceanic and Atmospheric Administration's polar orbiting meterological satellites. The sensors collect radiance data daily, at 4 km spatial resolution with global coverage. Daily collection is important, as it allows for selection of data for cloud-free days to minimize the effects of cloud cover. Tucker *et al.* have used these data to estimate the amount of intercepted photosynthetically active radiation (IPAR), the radiation in the spectral range that is strongly absorbed by leaves for driving photosynthesis. From this they estimate the green-leaf densities of plant canopies. If these factors provide an accurate measure of terrestrial photosynthesis, and if the annual CO_2 cycle is due mainly to photosynthesis variations, the satellite data should correlate well with atmospheric CO_2 variations.

The monthly, latitudinally-averaged values of a vegetation index derived from the data for the period 1982–84 have been compared with atmospheric CO_2 concentrations by Tucker *et al.* The patterns match well and show the expected inverse relationship: the higher the vegetation index, the lower the CO_2 concentration with a 1–2-month lag.

These remote-sensing techniques could potentially contribute to our understanding of the greenhouse problem in at least two ways. First, they could help in refining and validating global carbon-cycle models[4-6]. There is considerable uncertainty about how well the terrestrial biota is represented by these models; few detailed validations have been performed[2]. The global-wide data from the AVHRR sensors could provide an additional, independent data source against which CO_2 assimilation and release could be compared.

Second, they could be valuable for monitoring long-term effects of higher CO_2 concentrations and climatic change on the global vegetation. It is very uncertain whether and how the productivity of global ecosystems will be affected directly by higher CO_2 levels[7] — the CO_2-fertilization effect. In carbon-cycle models this effect is often represented by a simple one-parameter equation in which the assumed value of the biotic growth factor is estimated from results of greenhouse experiments. But scaling up the controlled experimental results from leaf or plant level to the real world of highly dynamic, interactive plant communities and ecosystems is fraught with difficulties[8]. The technique for monitoring changes in the productivity of global ecosystems could provide the empirical data with which to test the assumption of CO_2 fertilization.

Change in species composition or areal distribution of ecosystems could also be caused directly by increasing CO_2 levels and by climatic change. Such vegetation changes have obvious feedbacks to carbon reservoirs and fluxes as well. Again, the satellite data could prove useful for detecting any such shifts.

But the state-of-the-art in using the remote-sensing methods for relating reflected radiation, green-leaf biomass, primary production and atmospheric CO_2 levels is still immature. Tucker *et al.* note that unexplained variance and uncertainty exist at each link of this chain of relationships. How much confidence can we place in the approach? How much of an improvement over existing methods of measurement does it actually represent? Its biggest advantage is the global coverage, with fine resolution. But the sceptic must be convinced that we are not being sold sophisticated technology to address questions for which we largely know the answers.

Further careful comparisons of the satellite data with model results and ground-based data would help to establish the validity of the approach. Nevertheless, we have been given an enticing glimpse of a method with potentially far-reaching applications to the important global problems of the greenhouse effect and climatic change. □

Hydrogenases

From chemistry to legume growth

from R. Cammack and M.G. Yates

Hydrogenases are enzymes used by bacteria and algae either to produce hydrogen or to consume it as a fuel. They are of interest not only as natural organometallic catalysts and because of the possibility of their application to biotechnological hydrogen production but also because hydrogenase genes may be used to increase agricultural productivity by improving the efficiency of nitrogen fixation. A recent symposium in Hungary* illustrated how the study of these fascinating enzymes has progressed.

It is now clear that there are two types of hydrogenase. The first contains iron, is extremely active and occurs in anaerobic bacteria such as *Clostridium*, which produce H_2 as an electron sink during their metabolism. The second type, one of the few enzymes known to require nickel, is more widely distributed and is used principally for H_2 uptake. It is less active in H_2 production than the Fe-hydrogenase, but from the biotechnological point of view it has the advantage of being much less sensitive to oxygen.

The structural genes of the Fe-hydrogenase of *Desulfovibrio vulgaris* have been sequenced (C. Veeger, Agricultural University, Wageninen). They encode a polypeptide of relative molecular mass (M_r) 46,000 and a hitherto undetected small subunit of M_r 13,500. The sequence indicates that two of the iron–sulphur clusters in this enzyme are of the conventional [4Fe–4S] kind and similar to those in bacterial ferredoxins; the third cluster is probably involved in catalysis.

The probable catalytic site of the Fe-hydrogenase from *Clostridium pasteurianum* has been scrutinized by Mössbauer spectroscopy and magnetic circular dichroism spectroscopy (L.E. Mortenson and M.W.W. Adams, Exxon Research, New Jersey; B.H. Huynh, Emory University, Atlanta; M.K. Johnson, Louisiana State University). It seems to be a unique type of four-iron cluster in which one iron atom is in a different environment but coupled to the other three.

The mechanism of action of the Ni-hydrogenases of *Desulfovibrio* species has been studied by electron-spin resonance and other spectroscopic techniques (J.J.G. Moura, Centro de Quimica Estrutural, Lisbon; J. LeGall, CEN Cadarache, France; R. C.). The nickel centre, which from EXAFS measurements seems to be surrounded by sulphur ligands, can take up several oxidation levels including Ni (III) at an extraordinarily low redox potential. A hydride seems to be involved in the hydrogenase reaction mechanisms but its structure is not yet known.

What seems to be the commonest type of hydrogenase contains two subunits of M_rs about 30,000 and 60,000. Important examples are the membrane-bound Ni-hydrogenases, which have been isolated from the hydrogen-oxidizing bacterium *Alcaligenes eutrophus* (K. Schneider and H.G. Schlegel, University of Göttingen), the aerobic nitrogen-fixing soil bacterium *Azotobacter vinelandii* and the symbiotic nitrogen-fixing organism *Rhizobium japonicum* (D.J. Arp, University of California, Riverside). These enzymes prove to be similar in structure and antigenic characteristics, as well as in regulatory factors (O_2, H_2 and carbon substrates) and genetic determinants.

The genetics of hydrogenase has developed only recently. In *Escherichia coli* there are probably three different hydrogenases (D. Boxer, University of Dundee). Mutants in the structural genes have not been identified because a deficiency in one is masked by the presence of another, but several mutants in which the hydrogenase activity is affected have been isolated. Lee *et al.* have evidence of two classes of mutants, one of which contains *hydA* and *hydB* genes[1,2]. The *hydB* gene is probably in a single operon with a gene encoding formate dehydrogenase and another for an electron-transport protein that couples formate dehydrogenase to hydrogenase. Of two newly discovered genes, *hydC* and *hydD* (L.F. Wu and M.A. Mandran-Berthelot, CNRS, Villeurbanne), the former may be involved in Ni processing.

The *hup* genes of *R. japonicum* Ni-hydrogenase have been isolated[3]. Plasmids containing these genes complement Hup$^-$ mutants of *Azobacter chroococcum* and the arrangements of the *hup* genes in the genomes of these two species are similar[4]. The *hup* genes of *R. japonicum* are probably contiguous and comprise 15.5–21 kilobases divided into at least three transcriptional units[5]. The *hox* (hydrogen oxidation) genes of *Alcaligenes eutrophus* are plasmid-borne, encode both the membrane-bound and a soluble, NAD-linked hydrogenase and contain the structural and regulatory genes in a 50-kilobase sequence. However, an additional chromosomal function is necessary to express the Hox activity. This function may be part of a general regulatory mechanism analogous to the *fnr* system of *E. coli* (B. Friedrich, Freie Universität, Berlin). The *hup* genes of *Rhizobium leguminosarum* are also plasmid-borne, those of *R. japonicum* may be, but those of *A. chroococcum* and one *Alcaligenes* strain are not; *hup* genes have also been isolated from the purple photosynthetic bacterium *Rhodopseudomonas capsulata* (A. Colbeau, A. Godfroy and P.M. Vignais, Centre d'Etudes Nucleaires, Grenoble).

Interest in hydrogenase genes is stimulated by the possibility that hydrogenase might improve the efficiency of biological nitrogen fixation by symbiotic rhizobia in leguminous plants, such as soybeans; many strains of rhizobia are naturally Hup$^-$ or express low activity in legume nodules. The energy-intensive reaction of the enzyme nitrogenase produces hydrogen gas as an apparently inevitable by-product. If it builds up inside the soybean nodule, the hydrogen may inhibit the nitrogenase and it certainly represents a waste of energy resources. Hydrogenase, by recycling the hydrogen, could in principle alleviate these problems. But do *hup* genes produce bigger plants?

H.J. Evans and co-workers have investigated this question by comparing yields of soybean plants inoculated with Hup$^+$ or Hup$^-$ strains of *R. japonicum*. Both naturally occurring and genetically engineered Hup$^+$ and Hup$^-$ strains were used[6]. A range of responses was obtained with statistically significant higher yields in the *hup*$^+$ series in most cases. Parallel work on free-living *A. chroococcum* (M.G.Y.) shows that its hydrogenase aids growth under selective conditions; these are carbon-limited, nitrogen-fixing continuous cultures at high dilution rates, or growth intiation in batch culture under air, together with low levels of carbon substrates.

The complexity of the *hup* operon appears to be comparable with that of the nitrogen-fixing *nif* operons. The fact that they have common regulatory factors (O_2, fixed nitrogen and temperature) is probably coincidental, although Hup$^-$ Nif$^-$ mutants of *R. japonicum* are known[7]. Both the biochemistry and genetics of hydrogenase are important areas for continued research. ☐

The real cause of Ethiopia's problems

SIR—Constructive analysis and critical review by the scientific community of possible interventions to avoid future disasters in the drought-stricken African Sahel is the least that can be asked. John R. Krebs and Malcolm J. Coe[1] have certainly made a positive contribution to this process by assessing recent reports of the causes of the disaster, paying particular attention to the impressive argument of A.R.E. Sinclair and J.M. Fryxell[2] who proposed that the contesting causes are the weather and man. Krebs and Coe single out man and his recent efforts to develop sedentary agriculture as drawing the largest portion of the blame, but I suggest that much of their argument is not appropriate to the highland areas of Ethiopia so severely affected by the recent famine. Furthermore, the suggestion that a return to migratory lifestyle is the most viable option is unlikely to be considered feasible in those areas of Ethiopia.

Drought is not new to Ethiopia. However, Sinclair and Fryxell[2] argue that previous years of below-average rainfall did not result in the extreme mortality seen in the past 10 years. This is not the case. Ethiopia's chronicles and other historical sources reveal 23 major famines between 1540 and 1800, with those of 1540 and 1702 receiving particular comment as to their severity[3]. The famine of 1828–29 resulted in severe loss of life, and was complicated by an epidemic of cholera. The most devastating and well-described famine of 1888–92 reputedly killed one-third of the Ethiopian population[4] and was complicated by a plague of locusts and an epidemic of rinderpest in cattle which almost destroyed the cattle population.

In many of the northern areas prone to cyclical drought, there is either no tradition of migration in search of pastures, water and cultivable soils or the migrations are distinct from the pastoral migrations more characteristic of other areas of Sahelian Africa. Sedentary agriculture in this area was established in the tropical highlands long before the advent of aid programmes which, along with colonization, have been proposed as major causes of the Sahelian famines[1,2]. Ethiopia was never colonized, with the exception of a five-year occupation by Mussolini's forces. Extensive agricultural aid programmes are a relatively recent introduction and, judging from my three years' experience in Ethiopia a decade ago, have not had the impact, penetration and conequently destruction of the environment nd the ecological balance that have ocurred in many other parts of Sahelian frica. Environmental destruction has of urse occurred, as a result of high popution density, overgrazing, denuding of vegetation and soil erosion, but this has generally been self-inflicted and has occurred over a long time. The northern highland region of the country, also the most severely affected in the drought and famine of 1972–73, is relatively densely populated (more than double the average population density of sub-Saharan Africa), and much of it is characterized by plateaus at an altitude of 2,500– 3,000m, gorges, mountain peaks and deep chasms. The peasant inhabitants are engaged in sedentary subsistence farming[5], cultivating small plots of land, which as a result of centuries of feudal land tenure system and the traditional bequests of land, have become smaller with time. The farmers are hampered by the terrain and soil erosion occurs on an immense scale. Severe transport and communication problems associated with the rugged landscape compound their difficulties. They live, therefore, on the edge of survival.

The rainfall of the region is largely dependent on the movement of the Intertropical Convergence Zone (ITCZ) and its relation to pressure changes in the surrounding regions. Annual rainfall figures show very pronounced fluctuation from year to year, with variations of 56–140% of the mean figure reported during a 70-year period[2]. Failure of the rains is therefore inseparable from the man-made components of this disaster. Furthermore, whereas overgrazing in highland Ethiopia is undeniably part of the man-made contribution to the cause, it is not the result of recent settlement near waterholes as suggested by Sinclair and Fryxell[2].

I submit therefore that in Ethiopia it is impossible to label the drought hypothesis as a misconception and to separate it from the alternative settlement-overgrazing hypothesis in discussion of the cause of the secular famines in that country. Furthermore, I think that broad generalizations of the Sahel which include Ethiopia should consider the geographical, historical, sociological and political factors which render it distinct from many other countries of the region.

Nevertheless, full support should be given to the recommendation of Sinclair and Fryxell that the improvement of the environment over several decades must be addressed by both developed and developing countries. The specific suggestions will require unprecedented collaboration between donor agencies and a close coordination between these agencies and the appropriate government departments in individual countries which, if to include such measures as cattle depopulation, will require a heavy hand to counteract traditional customs and practices relating to cattle keeping[6]. (For years veterinary services have contributed to the improvement of cattle production efficiency by reducing the prevalance of many major infectious diseases but this has not been matched by corresponding improvement in livestock offtake and marketing.) But most important, the environmental improvement projects should be tailored to fit the individual countries, or in the case of Ethiopia, regions within the country, to avoid the undesirable effects of yet further inappropriate development aid such as that we are currently criticizing.

Major groove or minor groove?

SIR—After Matthews first proposed that cro protein has an α-helix that contacts the major groove of a right-handed B-DNA[1], it was soon realized[2] that the helix-major groove interaction might be a common feature by which many gene regulatory proteins recognize a particular sequence of DNA. Now we have the first crystallographic picture for this kind of binding in the studies on the phage 434 repressor–operator complex[3]. Although different in overall structure, endonuclease *Eco*RI has also been shown to have an α-helix contacting the major groove of its substrate[4]. I have suggested[5] that stereochemically the major groove of B-DNA does provide the best place for a sequence-specific DNA-binding protein to make extensive contact with a 'recognition helix' as the main determinant of specificity[6]. The argument is as follows[5]. First, the diameter of an α-helix is at least 10.7Å. Among common DNA structures, only the major groove of B-DNA is both broad and deep enough (about 11.7Å and 8.5Å) to accommodate an α-helix. Second, the major groove is much more specific than the minor groove for protein binding. This is because any type of mutation (A-T → T-A, A-T → G-C, A-T → C-G and C-G → G-C) changes the potential hydrogen bonding pattern much less in the minor groove compared to its effect on the pattern in the major groove. An extreme example is the A-T → T-A mutation, which keeps almost the same two H-donor positions in the minor groove but exerts a totally different hydrogen bonding pattern in the major groove. As for hydrophobic interaction, another important source of specificity, the main hydrophobic side chain (methyl thymine) of DNA lies in the ma- ove as well.

jor groove contact is not universal, however. If the the protein in question is not a sequence-specific one, the minor groove can also be its binding site, as reported by Klug and his colleagues in the histone core-DNA structure[8]. Also, proteins involved in transcription, reverse transcription and in the priming of DNA replication have a DNA-RNA hybrid as the binding partner. The hybrid molecule has been shown to assume A-form conformation[9]. Yet in A-conformation only the minor groove is open to proteins, while the major groove is too narrow and deep (2.7Å in width and 13.5Å in depth). Moreover, the two edges of the major groove are laced together by a continuous network of water molecules, making the major groove harder to access. It is then conceivable that the minor groove turns out to be the better binding site for those proteins. Since these DNA-binding proteins are not sequence-specific ones, the less specific minor groove is just good enough.

The facts on cystic fibrosis testing

Sir—The *News and Views* item[1] on a series of papers[2-5] reporting DNA probes showing linkage to the cystic fibrosis (CF) gene observes "a start has at least been made on the development of the prenatal test for cystic fibrosis". It continues "the new data offer immediate prospects for the prenatal testing of cystic fibrosis". The reader would be entitled to conclude first that no prenatal test for CF currently exists and second that advances in molecular biology have radically altered this situation. Neither conclusion is correct.

Two years ago we reported that measurement of microvillar enzymes in amniotic fluid supernatant could be used as an *in utero* test for CF[6,7]. Our data have been confirmed in many other laboratories and a special issue of the journal *Prenatal Diagnosis*[8] was devoted to this subject. Although the test is not perfect, it has a very adequate detection rate of 95% at 18 weeks of pregnancy and a false positive rate of 5%. In the past two years more than 450 at-risk pregnancies have been prospectively screened by our procedures, and the birth of over 100 children with CF prevented. With the possible exception of Tay–Sachs disease and β-thalassaemia, no other mendelian disorder has been as successfully tackled.

At first sight, it might seem that a restriction fragment length polymorphism (RFLP) tightly linked to the CF gene could improve prenatal testing by moving it from amniotic fluid samples in the second trimester of pregnancy to chorionic villus samples in the first trimester. However, this ignores a cardinal requirement of prenatal testing, namely that some method of confirmation of diagnosis on the abortus be available. This problem has been solved for the second-trimester fetus, first by the observation that most CF fetuses have the macroscopic appearance of meconium ileus[8], and second by protein and enzyme analysis of meconium samples scraped from the fetal ileum[9]. These anatomical and biochemical changes are probably specific to the second trimester and observable only on an intact fetus. If they existed in the first-trimester fetus (which we doubt) they could not be assessed in materials removed by vacuum aspiration, the procedure for termination at this stage of pregnancy.

It is difficult to see how CF-linked RFLPs make reliable prenatal diagnosis 'a reality'. The critical question of the possible genetic heterogeneity of the disease has yet to be addressed. There are suggestions in two of the papers reviewed[3,4] that the CF linkage relationship in the Amish may be different from that in other populations. Even if CF turns out to be a genetically homogeneous entity, much work needs to be done on producing highly informative flanking RFLPs, and on defining the extent of recombination expected with different types of multi-point analysis. But until the CF gene or its protein product is identified, the use of RFLPs on chorionic villus samples will lead to a form of prenatal testing without the benefits of confirmation of diagnosis. It must be emphasized that this is a radical departure from accepted norms of *in utero* testing.

We also have doubts about the value of RFLP-based heterozygote testing in CF. Here the need is for population-wide screening, so that heterozygous couples could be identified before the birth of the first affected child. Programmes of prenatal screening for Tay–Sachs disease and for β-thalassaemia have been effective, largely because heterozygosity tests have been simple, cheap and rapid. The current state of DNA technology is not yet suitable for this type of application.

There has been a tendency recently to exaggerate the immediate clinical benefits of advances in molecular biology. Careful assessment of the potential of RFLP-based diagnosis of genetic disease suggests that its role is likely to be drastically limited by a number of factors such as genetic heterogeneity, the need to have information on whole families rather than individual patients, and expense. Although localization of a mutant gene on a particular chromosome will undoubtedly assist attempts at cloning that gene and identification of its protein product, it must be noted that this is yet to be achieved for any unsolved mendelian disorder, and may well prove more difficult than has been anticipated.

Long-running experiments

Sir—Your coverage of long-running experiments (*Nature* **318**, 310; 408 (1985)) brings to mind an experiment that although begun in this century will probably not be complete for millennia.

In 1918 Howard and Daniels[1] devised the simple but ingenious idea of sealing nitric oxide in glass tubes, some of which contained potential catalysts. Nitric oxide is thermodynamically unstable ($\Delta G^{\circ}_{f\,298} = 86.6\,\mathrm{kJ\,mol^{-1}}$) and any decomposition resulting from $2NO \rightarrow N_2 + O_2$ would be followed by $2NO + O_2 \rightarrow 2NO_2$ and the brown nitrogen dioxide produced would be easily detectable. When the tubes were examined 40 years later, decomposition was found neither in tubes containing pure NO nor in tubes containing NO plus catalyst.

The result was no surprise because an extrapolation of their higher temperature work in the presence of a calcium oxide catalyst indicated that 70,000 years would be required for 2% decomposition (the minimum they could detect) at room temperature. Howard and Daniels gave some of their tubes to the Smithsonian Institution, Washington DC, for future examination. In the case of the homogeneous gas phase decomposition o NO at room temperature, even if w assume a detection system sensitive to 10 molecules of NO_2, it would still take ~10 years for any decomposition to be noticed

Current Topics in Microbiology and Immunology

Volume 122

The BALB/c Mouse

Genetics and Immunology

Editor: **M. Potter,** Bethesda
1985. 85 figures. XVI, 253 pages. Hard cover DM 126,-
ISBN 3-540-15834-0

Contents: History of the BALB/c Family. - Genetic Differences in BALB/c Sublines. - Differences in Response to Infections. - Immune Response Differences. - Plasmacytomagenesis and Response to Mineral Oils.

Volume 121

Bacteria and Complement

Editor: **M. Loos,** University of Mainz
1985. 76 figures. IX, 191 pages. Hard cover
DM 136,-. ISBN 3-540-15877-4

This volume contains the first synopsis of important aspects of host defence and how this system effectively acts against infectious micro-organisms. Its purpose is to bring together in one volume separate up-to-date reviews on the activation and effector phases of the complement system and the way these proteins are triggered off by the envelope structures of gram-negative and gram-positive bacteria.

Volume 120

Parasite Antigens in Protection, Diagnosis and Escape

Editor: **R. M. E. Parkhouse,** London
1985. 17 figures. 260 pages. Hard cover DM 168,-
ISBN 3-540-15859-6

Contents: Introduction. - The *Eimeria*. - *Entamoeba Histolytica,* Antigens and Amoebiasis. - Parasite Antigens, Their Role in Protection, Diagnosis and Escape: The Leishmaniases. - Parasite Antigens in Protection, Diagnosis and Escape: *Plasmodium*. - Toxoplasmosis: The Need for Improved Diagnostic Techniques and Accurate Risk Assessment. - Antigens of African Trypanosomes. - Antigens of Taeniid Cestodes in Protection Diagnosis and Escape. - Nematode Antigens. - Schistosomes: Surface, Egg, and Circulating Antigens. - Trematodes, Excluding Schistosomes, With Special Emphasis on *Fasciola.*

Volume 119

Images of Biologically Active Structures in the Immune System

Their Use in Biology and Medicine

Editors: **H. Koprowski,** Philadelphia; **F. Melchers,** Basel
1985. 22 figures. XI, 142 pages. Hard cover DM 96,-
ISBN 3-540-15760-3

The articles assembled in this volume offer new information on the potential practical applications of the network theory of the immune system. They report on the search for molecules and their biological functions and for the regulation of the immune response itself in autoimmunity and vaccination.

Volume 123

Retroviruses 4

new

Editors: **P. K. Vogt,** Los Angeles, **H. Koprowski,** Philadelphia
1986. 23 figures. VII, 98 pages. Hard cover DM 86,-. ISBN 3-540-15947-9

Contents: Interaction of the Rous Sarcoma Virus Protein pp60^{src} with the Cellular Proteins pp50 and pp90. - Microinjection Studies of Retroviral Polynucleotides. - The Viral Tyrosine Protein Kinases. - Homology Among Oncogenes.

By the same editors:

Volume 112

Retroviruses 3

1984. 19 figures. VII, 115 pages. Hard cover DM 72,-. ISBN 3-540-13307-0

Contents: Bovine Leukemia Virus. - Spleen Focus Forming Virus: Relationship of an Altered Envelope Gene to the Development of a Rapid Erythroleukemia. - The Genetics of Murine Leukemia Viruses. - Expression of Cellular Oncogenes.

Volume 107

Retroviruses 2

1983. 26 figures. VII, 180 pages. Hard cover DM 124,-. ISBN 3-540-12384-9

Contents: Acute Transforming Feline Retroviruses. - Asymmetric Chromosomal Distribution of Endogenous Retrovirus Loci in Chickens and Mice. - Subcellular Localization of pp60^{src} in RSV-Transformed Cells. - Regulation of Cell Growth and Transformation by Tyrosine-Specific Protein Kinases: The Search for Important Cellular Substrate Proteins. - Phosphotyrosyl-Protein Phosphatases.

Volume 103

Retroviruses 1

1983. 16 figures. V, 146 pages. Hard cover DM 104,-. ISBN 3-540-12167-6

Contents: Avian Endogenous Viral Genes. - Synthesis, Integration, and Transcription of the Retroviral Provirus. - Defective Avian Sarcoma Viruses. - Murine Leukemia Viruses with Recombinant env Genes: A Discussion of Their Role in Leukemogenesis. - Avian Acute Leukemia Viruses. - Molecular and Cellular Biology of Abelson Virus Transformation.

Volume 118

Genetic Approaches to Microbial Pathogenicity

Editor: **W. Goebel,** University of Würzburg
1985. 47 figures. XI, 283 pages. Hard cover DM 160,-
ISBN 3-540-15597-X

Volume 117

The Biology of Trypanosomes

Editor: **L. Hudson,** London
1985. 25 figures. X, 183 pages. Hard cover DM 124,-
ISBN 3-540-15512-0

What's in the name?

John A. Campbell

Artificial Intelligence: The Very Idea. By John Haugeland.
MIT Press:1985. Pp.289. $14.95, £14.95.

AMONG scientific subjects, artificial intelligence has one unique distinction: it has been the victim of its own name. Because the name comes straight from everyday language, too many people have found futuristic messages in it merely through the associations that occur when "intelligence" and "artificial" are coupled together. The results have included science-fiction interpretations and unreasonable expectations of the subject, and confusion of what has been achieved with what has not. Quite rightly, some of the founding fathers have conceded, at least in private, that not enough care was taken 30 years ago to find a label free of loaded words.

But is there any future in Artificial Intelligence, Baron Frankenstein?

Among specialists, there are at least three different definitions of what artificial intelligence involves. One is the study of human intelligence through the use of methods and metaphors depending essentially on computers and computation; this admits both a middle-of-the-road view, in which the definition means neither more nor less than what it says, and a man-in-the-black-box view, whose meaning is self-evident. A second definition is subtly different on paper but very different in practice: the computational study of tasks and processes which have previously been observed only in association with human intelligence. The third has arisen as a result of the subject's actual successes, and the observation that some concepts and techniques have recurred in many of the best pieces of work. By this modest operational definition, a project is an example of artificial intelligence if it relies mainly on those concepts or techniques. (A collection of this information, deliberately expressed in English rather than some high-level programming language, is given by P.H. Winston in the second edition of *Artificial Intelligence*, published by Addison-Wesley in 1984.)

The first definition is closest to the popular impression of what artificial intelligence is. It may even be a surprise to non-specialists to learn that the other two exist, the main reason being that books intended for a general audience and taking either of them as their starting-point have not been very visible in the past. Haugeland's book does not fill this gap. Instead, it joins the queue (or, rather, the unruly crowd) attached to the first and most adventurous definition. It is, nevertheless, a welcome newcomer, because of its relative moderation and avoidance of science fiction.

As no exploration of the consequences of the definition can go far without touching on questions which were once regarded as lying exclusively within philosophical territory, it is an advantage that Haugeland's background is that of a philosopher. On previous evidence, such a vantage point has been no guarantee of successful writing on artificial intelligence — indeed, it seems rather to have guaranteed frequent encounters with the technical and even philosophical banana-skins that litter the field — but Haugeland arrives almost undamaged at the finishing line in this obstacle course.

His central concern is to explore the connection between intelligence and the idea of thought as a formal or at least rational manipulation of symbols. A first chapter on the evolution of philosophical views of "mind" is therefore followed by straightforward description of some of the symbol-manipulating systems, such as Turing machines, that have had the most influence on theoretical computer science and computability. There is also a simple account of models of computation, which makes the point that today's standard computer architecture, not well adapted to any of the definitions of artificial intelligence, is easy to replace with alternative designs that perform better in simulations. This is not news to specialists in advanced computing and to people familiar with the Japanese Fifth Generation plan, but it deserves repetition for a general audience.

As a basis for his substantive arguments, Haugeland's tour of the history of theoretical computer science is less satisfactory than his discussion of issues where he is surer of his philosophical ground. In the historical sections, for example, Alonzo Church is short-changed (by omission) on two counts and possibly three, with partial compensation for this Churchless picture only in the footnotes (where there is still confusion about the difference between Turing's "thesis" and Church's thesis, among other lesser things). Computer scientists may have the sense of seeing their subject through frosted glass here, but at least the author's heart is in the right place. And there is plenty of nourishment in the footnotes in general, collected conveniently at the end of the book, they can be sampled like a chariot of desserts.

The main value of the book to both specialists and non-specialists lies in the attention given to the two principal difficulties of current research in artificial intelligence. These are the frame problem, which is the problem of knowing how to link an item of information efficiently with all the other items that may be needed to establish the context in which its meaning may be determined properly, and the problem of how to assign and manipulate meanings (semantics) of expressions whose rules for structural (syntax) transformations are spelled out in formal symbol-manipulating systems. The problems themselves are well described, so that a general reader can appreciate the irritation that they cause to researchers, especially in speculation on how the human brain solves or avoids them. Haugeland weighs the balance of impressions justly: he is a pessimist rather than an optimist, but admits that, on the evidence, the basic questions of the achievability of "artificial intelligence" remain open.

While contexts and meanings may complicate work in artificial intelligence, there are both possible and desirable ways of reducing the complexity. On the "possible" level, problems of how to represent meaning may become much more tractable if the basic semantic operation used in a formal computational system, or even a brain, is nothing more than a two-way choice or distinction between alternatives or stimuli. And artificial-intelligence research can desire nothing better of its spectators than that they agree to replace the subject's label with one that calls up no wild associations. "AI" for "artificial intelligence", say? The very idea! □

John A. Campbell is Professor in the Department of Computer Science, University of Exeter, Exeter EX4 4PT, UK.

Two brains but of a single mind

John C. Marshall

The Duality of the Mind. By A.L. Wigan. Foreword by Joseph Bogen. *Joseph Simon, PO Box 4071, Malibu, California 90265, USA: 1985. Pp.346. $35.*

THE question of how many angels can dance on the head of a pin has long since ceased to exercise our finest scholars. Yet if one wanted a contemporary analogue the following might suffice: how many minds may a man (or woman) manifest? "One", said René Descartes; "Two", said Arthur Wigan and Roger Sperry; "Forty-two", said Franz-Joseph Gall.

The answer "Two" was sanctified by the award of the 1981 Nobel Prize in Medicine and Physiology to Sperry for the work that he and his colleagues had undertaken on commissurotomized patients. Some 20 years earlier, the eminent Los Angeles neurosurgeon Joseph Bogen had succeeded in reducing the incidence of major convulsive seizures in a small group of severely epileptic patients by sectioning the main cortical fibre tracts (commissures) that connect the two hemispheres of the brain. Sperry's intensive testing of the cognitive functions of these patients' now-disconnected cortices sparked a veritable explosion of interest in the differential psychological capacities of the left and right cerebral hemispheres. On one account of the results, Bogen's operation did not *create* two minds within a single body but rather revealed that we are all dual creatures, deluded in our belief that each of us is an indivisible self.

Bogen's (or Bogens') own interest in these issues has extended beyond the investigation and interpretation of his "split-brain" patients to include the history of neurological speculation about cerebral duality. One fruit of his delving into the past is this splendidly handsome reprint of Arthur Wigan's Victorian epic of 1844, the scope and character of which is best shown by its full title: *A New View of Insanity: The Duality of the Mind Proved by the Structure, Functions, and Diseases of the Brain and by the Phenomena of Mental Derangement, and Shown to be Essential to Moral Responsibility.* Indeed, Wigan's version of the "two-brain" theory is sufficiently close to some modern accounts for Bogen to name his own position "neowiganism".

Who might want to read the book today? To begin with, anyone who is concerned with the relationship between the neurosciences and society will be fascinated to see Wigan struggling to resolve the tension between biological determinism, educability and moral choice. Wigan's phraseology, and the certainty of his Victorian belief in scientific and ethical progress, may seem quaint to our more cynical ears:

> The only limit to our researches on the nature of the mind, will ultimately be the boundary fixed by the Almighty to the powers of the human intellect — a point from which we are yet immeasurably distant. When we shall have cultivated all the faculties which He has bestowed upon us, to their full extent and perfection, then indeed will come the Millennium — an issue towards which we are steadily and rapidly advancing. . . . ;

yet his discussion of the potential conflicts between humanistic and scientific approaches to psychiatry and neurology is a good deal more honest and open than many current positions.

Second, the book *should* be read by all students of neuropsychology. Wigan is a pre-modern in that his work pre-dates the discovery of complementary hemispheric specialization that became (and remains) the central dogma of human neuropsychology. Thus the notion that the left hemisphere is primarily implicated in language functions and the right in visuospatial functions is quite alien to Wigan's time. For Wigan, the hemispheres are full duplicates with respect to their intrinsic cognitive capacities; it is solely "slight inequalities" of "form, energy, and function" that suffice "to produce all the varieties of character which are to be found in the world". Accordingly, many of the case reports that Wigan describes are directed towards showing that "One cerebrum may be destroyed, yet the mind remain entire". The contemporary student would benefit greatly from the exercise of contemplating whether Wigan's conclusion derives merely from inadequate testing of non-verbal skills or rather contains an important truth that has been buried under our own obsession with complementary specialization. □

A southern man

Derek Fordham

Shackleton. By Roland Huntford. *Hodder & Stoughton/Atheneum: 1985. Pp.774. £19.95, $29.95.*

"MEN wanted for hazardous journey. Small wages, bitter cold, long months of complete darkness, constant danger. Safe return doubtful. Honour and recognition in case of success." Thus Sir Ernest Shackleton chose to launch his 1915 Imperial Trans-Antarctic Expedition and was overwhelmed by thousands who wanted to join.

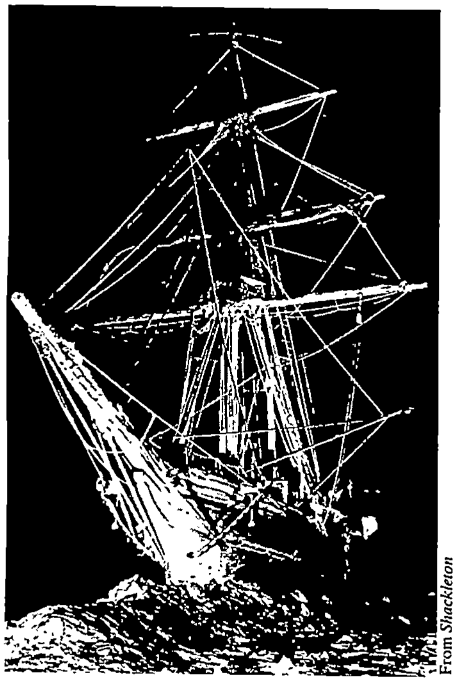
Years earlier, in 1900, Shackleton had been in the Antarctic for the first time and Roland Huntford spares no one in setting out the dreadful deficiencies and incompetence of that *Discovery* expedition under the leadership of Commander Robert Falcon Scott. During the expedition Shackleton came close to death and subsequently suffered the ignominy of being invalided home on Scott's orders. Scott's action was undeniably motivated by his dislike of Shackleton, who had shown himself to be a natural leader, in which respect Scott rightly doubted his own abilities.

In a spirit of defiant rivalry, heavily in debt and with a suspected weak heart, Shackleton set about organizing his own expedition, which sailed south in 1907. Shackleton and his team, poorly equipped and ill-prepared, penetrated to within 97 miles of the Pole before he decided to turn back, the hardest decision he ever had to make, but inescapable if he was to bring his team back alive. In so doing he laid bare the geography of the polar plateau and opened the route to the Pole for Scott and Amundsen to follow in 1911. His hero's return was marred by financial difficulties and the scandal of an errant brother, suspected of stealing the Irish crown jewels.

His resources in the face of failure were taxed again in October 1915 at the start of The Imperial Trans-Antarctic Expedition, when his ship, *Endurance*, having drifted helpless for 1,500 miles trapped in the pack-ice, was crushed and sunk in the Weddell Sea. For 600 miles Shackleton led his men over shifting, breaking ice to the floe edge and then across the storm-swept open sea to the desolation of Elephant Island. Having established his men in a primitive camp he set off a few days later with five companions on a further 700 mile open boat journey across the Southern Ocean to South Georgia. A final desperate traverse of a range of unmapped icy mountains led to the whaling station from which the rescue of his expedition was mounted. Shackleton the survivor had once again brought his men back from the prospect of certain death.

But a world on the brink of war failed to recognize the staggering accomplishment of this impetuous man and he had to struggle to raise further funds for his last expedition, during which the misfortunes encountered on his earlier Antarctic forays took their toll. He died as his ship reached South Georgia, ironically the scene of his return from the dead in 1916.

This is Roland Huntford's second polar book — the first, published in 1979, having left the schoolboy image of Captain Robert Falcon Scott somewhat mangled and the subject of much controversy — and deals with the very different but no less intriguing figure of a man who mixed Irish dreaming and poetry with the power to inspire those who worked with and for him in a manner previously unknown in polar exploration. The differences between Shackleton and Scott are developed and the author sees the comparison between the upright, unsure naval officer and the breezy, extrovert Irish poet as illustrating how, in an age before technology came to dominate polar exploration, Shackleton's great achievement was to break by sheer power of leadership and commitment to his objectives the mediocrity that had until then laid its dead hand over much British polar activity. It was not without reason his men called him simply, "Boss".



From Shackleton

Ice-bound: Endurance *trapped by pack-ice in the Weddell Sea.*

This is an impressive work and will surely stimulate new interest in a man whose achievements in the field of polar exploration have down the years been largely overshadowed by the tragic nature of his former leader's death.

On the crossing of South Georgia, which ended the journey for which above all else the world should remember Shackleton, he and his two companions felt they were accompanied by an extra person. This is a not uncommon experience for explorers under stress, and Shackleton's account of this phenomenon inspired a haunting reference in T.S. Eliot's poem, *The Wasteland*, "Who is the third who walks always behind you?".

Perhaps for "The Boss" it was the embodiment of the conventional hero, which his enigmatic spirit never quite embraced. □

Derek Fordham, 66 Ashburnham Grove, Greenwich, London SE10 8UJ, UK, is Secretary of the Arctic Club.

States of alteration

C. Ladd Prosser

Changes in Eukaryotic Gene Expression in Response to Environmental Stress. Edited by B.G. Atkinson and D.B. Walden. *Academic: 1985. Pp.378. $71.50, £60.*

The Adaptive Role of Lipids in Biological Systems. By Neil Hadley. *Wiley: 1985. Pp.319. $39.95, £41.40.*

ATKINSON and Walden are concerned with the control of protein synthesis and, as the basis for discussion, the contributors to their book have focused on proteins made in response to stress. It was observed 30 years ago that brief exposure to heat brings about puffs on salivary chromosomes of *Drosophila* and leads to the synthesis of several proteins in large quantity — the so-called heat-shock proteins. In *Drosophila*, seven proteins of different molecular weights have been identified and several have now been cloned. Although most information on heat-shock proteins is available for *Drosophila*, and this is reflected in the book, other chapters describe heat-shock proteins in a slime mould, sea urchin tissues, amphibians, birds and mammals, and in plants.

The heat-shock proteins in different organisms are of various sizes but the most prevalent one is of 70 K molecular weight. They are highly conserved and can be induced by heat exposure of isolated cells as well as of intact organisms. Control has implicated both translation and transcription but evidence from inhibitors emphasizes the increase in transcription of specific mRNAs as most critical. It appears that heat exposure turns on certain genes and one effect of the synthesis of heat-shock proteins is to repress action of mRNAs for other proteins. The chapter by Lindquist and Didomerico on gene expression in *Drosophila* uses synthesis of the mRNA for the 70 K protein as a model for gene regulation in general. The *in vitro* induction of heat-shock proteins in avian red blood cells is covered in chapter by Atkinson and Dean. In mammals, a fever of only 2°C is sufficient to induce heat-shock proteins in the brain.

Synthesis of these proteins is stimulated by other stresses, particularly toxins and drugs, hence the term stress proteins may be more appropriate than heat-shock proteins. Less is known of their synthesis in plants than in other organisms, but maize seedlings and soybean embryos do produce them. There seems no doubt that synthesis of heat-shock proteins is associated with increased resistance to heat stress. Although much is known of the sequence of specific gene activation and protein synthesis, the mechanisms by which heat-shock proteins protect against the lethal action of heat remain mostly speculative. But Atkinson and Walden have succeeded well in integrating the groundwork essential for a final answer to the question of mechanism within the seventeen chapters of the book.

Adaptation in a different system is the topic of the volume by Hadley. He has considered the adaptive function of lipids in a number of biological roles. The book could serve well for one part of a course in comparative physiology. The treatment of biochemistry of lipids is adequate for physiology students but probably not sufficient for lipid chemists. Lipids, predominantly phospholipids, constitute 25–75% of cell membranes by weight. The lipid composition of plasma and organelle membranes can be altered by nutrition and by temperature, but the way in which membrane lipids modify the functioning of membrane proteins remains an unsolved problem

A useful chapter on surface waxes precedes a detailed discussion of the role of waxes in the water relations of terrestrial plants and animals. Their protective role against evaporative loss of water is made clear, but the significance of the diversity in composition of surface waxes — hydrocarbons, ketones, esters, alcohols, sterole and triterpenes — is not explained.

Lipids, especially triglycerols, are stored as fuel that can be accumulated at certain times, for example at the pre-migration stage in insects and birds. Several roles for fat tissue are further described. Brown fat is a ready source of heat, present in most mammalian neonates and hibernants. Because fat has low thermal conductivity it is an insulator, especially in aquatic and cold-dwelling mammals. Some marine plants and animals are neutrally buoyant because of low-density fats. Buoyancy is implemented by an increase in total body lipids and by deposit of lipids of low density. A use of lipids not often considered is in chemical communication, especially in pheromones; some esters of plants are insect repellents. A final chapter deals with medical aspects — pulmonary surfactants, bile salts, fat absorption.

The overall impression to be gained from this book is of the extreme diversity of structure and function of biolipids. Clearly, this is a field of research in which comparative biochemists and ecophysiologists can profitably cooperate. □

C. Ladd Prosser is Emeritus Professor of Physiology in the Department of Physiology and Biophysics, University of Illinois at Urbana-Champaign, 524 Burrill Hall, 407 South Goodwin Avenue, Urbana, Illinois 61801, USA.

• *Ancestors: The Hard Evidence*, the proceedings of a symposium held in April 1984, has been published by Alan R. Liss/Wiley. The meeting was attended by leading workers in palaeoanthropology and was reported in *Nature* 208, **309** (1984). Editor of the book is Eric Delson, price is $49.50, £38.

Talking of muscles and motion

R.M. Simmons

Design and Performance of Muscular Systems. Edited by C.R. Taylor, E. Weibel and L. Bolis. *The Company of Biologists Limited: 1985. Pp.412. £25, $60. Available from the Biochemical Society Book Depot, PO Box 32, Commerce Way, Colchester CO2 2HP, UK.*

One of the main themes of this book, which is based on papers presented at the Seventh International Conference on Comparative Physiology in June 1984, concerns problems of gait during locomotion, such as why animals adopt narrow ranges of speed for particular gaits and why they change from one gait to another (Cavagna, Hedlund, McMahon and Taylor). Some of the illustrations are drawn from unusual human gaits such as hopping, Groucho running (that is, with very bent knees like Groucho Marx) and running on very compliant surfaces.

One idea, now 10 years old, is that an animal can be considered during locomotion as a multi-jointed mass-spring system with a characteristic resonant frequency, and thus a preferred stride rate. As speed increases, say in walking, the ride becomes uncomfortable and less economical because of the stiffness of the spring arrangement and running is more comfortable as the ride is softer and it is less costly in energy consumption. Maximum speed might be determined by maximum stress and this varies with body size much as expected (Alexander). Under the mass-spring model, unusual gaits extend the range of observations.

In locomotion on a flat surface the net external work done is small, but groups of muscles alternately shorten and are stretched thus performing positive and negative work respectively. The tuned-spring model implies that energy imparted to muscles by stretch is recovered when they shorten; indeed, this was first demonstrated in Margaria's laboratory 20 years ago. The positive work phase can thus appear surprisingly efficient, up to 70% in large animals, though much lower in smaller animals for reasons that are not entirely clear. More details of the process of energy storage come from experiments on isolated muscles (by Cavagna and his colleagues), showing increased energy output when an actively contracting muscle is first stretched before being allowed to shorten, some of the power coming from elastic energy stored in the tendons and some apparently stored in the cross-bridges.

Another theme in the book concerns the properties and determinants of the two main muscle fibre types in mammals, the fast-twitch fibres whose mechanical properties are fast and whose metabolism is mainly glycolytic, and the slow-twitch fibres which are slower and are mainly oxidative. The current state of knowledge about structural protein isoforms is given by Perry and Whalen, but most of the new findings about the proteins in mammalian muscle are concerned with mitochondrial enzymes: in separate studies Pette and Edgerton agree that the heterogeneity found in a given fibre type implies a different mode of specification than for the structural proteins, but disagree about whether fibres innervated by branches of the same nerve show heterogeneity. Kushmerick presents his now completed study of the energetics of isometric contractions in two muscles from the mouse, one predominantly slow and the other fast.

A third theme concerns the malleability of the system. Muscles predominantly of one fibre type can be converted into the other by cross-innervation or by changing the pattern of muscle activation artificially: continuous low-frequency stimulation yields slow-twitch charateristics, whereas occasional bursts of stimulation make for fast-twitch fibres. The major determinant of muscle speed is the myosin isoform, while the duration and rapidity of response to a stimulus is probably determined by the membrane systems.

From painstaking stereological measurements it appears that the membrane systems change before the structural proteins (Eisenberg): this can induce an abnormally high mitochondrial content in a fast to slow transformation, the muscle's response to the energetic demands caused by more frequent stimulation and longer response times while fast-cycling myosin is still present. A similar type of mismatch arises during early postnatal development in the rat if a nerve is crushed and then allowed to re-innervate a muscle (Vrobova). The pattern of motorneurone activity is changing during this period, so that by the time re-innervation is complete the immature muscle encounters a mature rate of stimulation and partial atrophy results. In the adult, complete recovery results, the reverse of what might be expected intuitively of variation in plasticity with age.

The sequence of appearance of myosin isoforms during development now seems well established (Whalen). Development from embryonic through neonatal to fast myosin occurs whether or not the muscle is innervated, but induction of slow myosin is nerve-driven. However, thyroid hormone is needed for the transition from neonatal to adult fast myosin. A recent report (discussed here both by Howald and Goldspink) describes changes in myosin isoform from slow to fast as a consequence of training in the rat, but changes in man seem to be less pronounced. Successful athletes in endurance events, such as long-distance runners, have a preponderance of slow twitch fibres and sprinters have more fast twitch fibres. Training in man can induce selective fibre type hypertrophy and an increase in mitochondrial content (Gollnick, Hoppeler), but it is still not clear whether an athlete's fibre typology selects the best event for him or the athlete selects the typology for his chosen event by training.

Other aspects of muscle performance such as whole body response and the control of movement are also covered by appropriate experts. There are in all 34 articles, mostly by different authors, and although the introductory chapters (by H. Huxley, Peachey and Wilkie as well as those by Perry and Whalen already mentioned) are good, I think the novice might find it hard to follow the threads of some of the arguments. For the professional and others with some background in the fundamental properties of muscle, however, this book offers some valuable insights into the design and performance of muscular systems. ☐

R.M. Simmons is Head of the Department of Biophysics, Cell and Molecular Biology at King's College London (KQC), 26–29 Drury Lane, London, WC2B 5RL, UK.

Edwin Hubble: legal eagle

from N. Hetherington

Edwin Hubble skilfully employed trial tactics and techniques to attain favourable verdicts from the court of science.

THERE is more to the advance of science than new observations and new theories. Ultimately, people must be persuaded.

Galileo, a master polemicist, appealed skillfully and effectively to a public forum when science, yet to be differentiated from philosophy, was still accessible to most educated people. An explosion of knowledge and specialization has since narrowed the body from which competent jurors can be drawn for the trial of a scientific idea. Yet, whether before the public or before a jury of their peers, scientists are still concerned with persuasive presentation.

The twentieth-century astronomer Edwin Hubble well appreciated the advocative aspect of science and was a skilled practitioner. Reading Roman law at Oxford and practising as an attorney in the United States were good preparation for a subsequent career in science. Trial tactics and techniques gained for Hubble favourable verdicts more quickly than might otherwise have been attained.

Independent witnesses

Hubble's bold extrapolations from near to distant galaxies presumed uniformity within the universe, a uniformity somewhat supported by Hubble's own studies at the Mount Wilson Observatory of the distribution of absolute magnitudes among isolated nebulae. Harlow Shapley at Harvard, however, had reasonable doubts. Hubble, attempting to persuade doubters with independent corroboration, emphasized, perhaps even exaggerated, the independence of Nick Mayall's study at the Lick Observatory.

Hubble had supported Mayall's dissertation proposal, and Mayall's analysis of nebular counts turned out to agree reasonably well with Hubble's own data[1]. When it came to publishing Mayall's results, though, Hubble contrived to have the study appear as a completely independent body of work. Thus it might more strongly persuade astronomers in the eastern United States, including Shapley. Hubble wrote to Mayall[2]:

> your investigation should be considered as absolutely independent of our work here. Actually it would have greater influence on the eastern gang if there were a note of challenge.

Thus was Mayall's evidence presented in court, to Hubble's satisfaction[3]:

> I am glad to hear that the thesis will be in print soon and thoroughly agree with the committee that it should be published without reference to my paper. Actually I have a personal interest in this decision for I am eager to have as much independent investigation as possible so that the accumulating evidence will eventually convince the eastern group of the importance of careful work. It was partly for this reason that I suggested so pointedly that you keep a skeptical point of view and look for discrepancies rather than consistency.

Mayall's corroborative evidence, independent in appearance, would weigh more favourably with the jury.

Cross-examination

Another of Hubble's discoveries to face trial was his calculation of great distances to spiral nebulae using the period–magnitude relationship for Cepheid stars. This was a major scientific revolution. Shapley, receiving the news in a letter from Hubble, said "here is the letter that has destroyed my universe"[4]. The focus of research at Harvard and elsewhere abruptly shifted from the local area to distant galaxies. The only evidence against Hubble's great distances was van Maanen's asserted detection of motions in spiral nebulae[5]. "So a consistent picture of the spiral is built on the basis of the Cepheid criterion ... save for a disturbing shadow cast by the measures of Mr van Maanen", wrote Hubble in notes for a talk before colleagues at Mount Wilson.

The shadow could be shortened, by stripping away the corroboration claimed by van Maanen[6]. Hubble found only one of the corroborations deserving of consideration, and in it the probable error exceeded the mean motion measured. Another study was vitiated by internal inconsistencies and in two others measured motion was in the opposite direction to that reported by van Maanen. Hubble later wrote, in a manuscript never published, that "reference to these [claimed corroborations] as 'similar motions', implying corroborative evidence, indicates an uncritical imagination"[7].

Edwin Hubble, photographed by Jay Barrie, from the posthumous The Nature of Science and Other Lectures *(Huntington Library, San Marino, 1954).*

Additionally, van Maanen claimed corroboration by Seth Nicholson, a colleague at Mount Wilson who had checked some of van Maanen's measurements. Hubble, though, observed that Nicholson's measures gave "results within the uncertainties of the material and hence do not themselves definitely indicate rotation"[7].

Van Maanen took Hubble's criticism "in a wildly personal manner"[8]. Shapley, a friend of van Maanen, was also disturbed, and felt that Hubble could afford to be less openly critical[9]. At first, Hubble was. Mrs Hubble later remembered that[10]:

> It was, the contradiction, not very important in the long run. The work had become so obvious and so extensive that van Maanen's measurements could be ignored ... Van Maanen had refused to discuss the subject or to re-examine his work. Edwin had decided to ignore the discrepancy for the time and go on with his work. A friend of his told me years afterwards that he [Hubble] said to him 'They asked me to give him [van Maanen] time. Well, I gave him time, I gave him ten years.' He [Hubble] knew the measurements were wrong, his close colleagues knew. To him that would be enough. To publish would be to expose van Maanen to public humiliation

But the ten years passed and van Maanen's measurements remained. Indeed, they may have begun to draw support once again. As Hubble explained:

> When a speaker at the RAS [Royal Astronomical Society] announced, if it were not for van Maanen's measurements, Hubble's results might be accepted, I decided to make the measurements.

Hubble had come to fear loss of support for his work unless van Maanen's contradictory evidence were challenged. Another potential loser was the Mount Wilson Observatory if Hubble and van Maanen were to engage in an unseemly public quarrel. Frederick Seares, editor of Mount Wilson publications, ruled Hubble's prosecution of van Maanen out of order[11]:

> For two men in the same institution there is opportunity for personal contact and for direct examination of each other's results, and hence for the private adjustment of differences in opinion. The institution itself it seems to me, is under obligation to see that all adjustment possible be made in advance of publication. If agreement cannot be attained it may be necessary for the institution to specify how results shall be presented to the public. In that event, however, there must be opportunity for the expression

> of individual opinion, but any such expression should be concerned only with the scientific aspects of the question at issue.

It seems Hubble was not completely happy with the decision, as Seares added[11]:

> The institution has, I think, the right to enforce this procedure; but in certain cases it may be wiser to waive its technical right and say to a dissatisfied individual, 'Print what you like, but print it elsewhere'.

Hubble needed to rephrase his questions of van Maanen, at least in Seares' courtroom.

Faced with the choice between leaving van Maanen's work unchallenged or challenging it directly in an ungentlemanly manner, Hubble found an ingenious solution. He made new measures and included Nicholson in the effort[12]. Thus a former witness for the defence was to give testimony favourable to the prosecution. Nicholson did not explicitly recant his earlier evidence or van Maanen's claimed corroboration, but jurors could easily have formed that impression. Hubble may have hoped they would. And, by using indirect implication rather than direct criticism, Hubble avoided alienating the jury of scientific peers with an explicit attack on a colleague.

In a brief paper immediately following Hubble's, van Maanen in a face-saving gesture presented new measures in partial confirmation of his own while conceeding that "it is desirable to view the motions with reserve"[13]. It was more a plea of *nolo contendere* than of innocent or guilty. Obviously the revised pleading had been negotiated with Hubble.

Innocent by implication

In another case Hubble also encouraged jurors to hear more than the witness said, and less. The otherwise puzzling appearance of colleagues ostensibly to verify a calculation scarcely requiring verification becomes understandable as a bit of legalistic legerdemain in aid of the establishment of the velocity-distance relation.

An increase in the red shift or velocity of extragalactic nebulae proportional to their distances from the Solar System had been discussed by the Dutch astronomer Willen de Sitter as early as 1917[14,15], and in 1924 Ludvik Silberstein at Rochester had attempted to establish de Sitter's predicted velocity-distance relation using globular clusters[16,17]. Silberstein, however, had not used all the data available and he had excluded three clusters with velocities not consonant with the theory he was attempting to prove. Strömberg[18] and Lundmark[19] at Mount Wilson found no correlation between the radial velocities and the distances of globular clusters.

They carefully distinguished Silberstein's discredited work from the general hypothesis of a velocity-distance relation. A conclusive test of de Sitter's hypothesis would have to wait a determination of distances of spiral nebulae because globular clusters might not be distant enough to have a measurable velocity-distance relation. Nevertheless, theoretical preconception such as had influenced Silberstein's analysis was suspect.

Motivated by de Sitter's theory, Hubble had Humason at Mount Wilson systematically observe faint and more distant nebulae to see if they had larger velocities than closer nebulae. Yet in 1929, in the resulting report, Hubble emphasized empirical aspects of his work[20]. Humason published his measures separately[21], so Hubble could refer to them as independent evidence. Not until the final paragraph did Hubble mention de Sitter or theory, then noting that the velocity-distance relation might represent the de Sitter effect and might be of interest for cosmological discussion. An understated introduction to the key to the scientific exploration of the universe!

Hubble did emphasize from the beginning paragraph a connection between his velocity-distance relation and earlier determinations of the motion of the Sun with respect to the extragalactic nebulae involving a velocity factor, the *K* term, apparently varying with distance. The *K* term now was largely irrelevant, because Hubble's new data indicated a linear correlation between velocity and distance regardless of whether the velocities were corrected for the solar motion. Intended or not, the *K* term served as a red herring, diverting attention from suspect theoretical considerations. It also provided an opportunity to introduce Strömberg and Lundmark as witnesses.

Hubble used the assumption of a velocity-distance relation to determine the solar motion relative to two groupings of nebulae. The two calculations produced approximately the same result, thus tending to confirm the assumption. Hubble mentioned that Strömberg had checked the general order of the values using different groupings of nebulae. Hubble did not state explicitly that Strömberg accepted the assumption of the velocity-distance relation, though readers could easily have leapt to that implication.

Lundmark could not be brought into court as readily, since he had by now returned to Sweden. But Hubble could cite Lundmark's solution for the solar motion. No matter that it differed from Hubble's solution, or that Lundmark had used a velocity-distance relation different from Hubble's simple linear proportionality. Hubble did not emphasize these differences to the jurors. Nor did Hubble reveal that he generally distrusted Lundmark's work[22]. What Hubble wanted was Lundmark's appearance on the stand as a friendly witness, not any actual testimony.

Certainly Hubble required neither Strömberg's nor Lundmark's assistance to check the straightforward calculation of the solar motion. The testimony c Strömberg and Lundmark was nc necessary. The presence of Silberstein' critics, though, implied that Hubble' work did not suffer from the same fault:

Hubble's establishment of an empirica velocity-distance relation, although begu in a climate of scepticism and suspicior proceeded smoothly and quickly. Withi two years, Hubble had decisively won ove the jury of scientific opinion. The scientifi case was outstanding, and it did not hu to have it argued by a skilled barrister.

Hubble later described modern scienc in the language of law, writing that scienc deals "with judgments on which it is poss ible to obtain universal agreement" an "agreement is secured by observation an experiment—impartial courts c appeal"[23]. He made the observations an experiments necessary to win his case: and skillfully argued the cases.

If Hubble's orchestration of evidenc appears unusual, it is because of the cor ductor's skill and the audience's incom plete view of science. No doubt man scientists orchestrate their evidence Hubble's orchestration is unusual in th degree to which it has been analysed.

It is not a matter of the fabrication c falsification of data, nor the use of fudg factors. Hubble's data was honest. And he tilted the playing field upon which h interpretations of data battled others, often was to restore a balance, to overcom prejudice against his ideas or in favour c others and to attain a fair hearing.

The propriety of any particula orchestration of evidence may be que: tioned. Perhaps a heroic image of pristin science excludes all orchestration c evidence. But advocacy is an integral pa of real science, not to be judged good c bad but to be recognized and studied.

Is the galactic centre black hole a dwarf?

David A. Allen* & Robert H. Sanders†

A 2.2-μm image of IRS 16, the relatively blue infrared source near the galactic centre, is presented at the highest spatial resolution yet reported. It comprises several discrete, extended sources. By intercomparison of radio and infrared images of the region, the non-thermal radio source Sgr A can be located relative to IRS 16 without the uncertainty of intermediate astrometric frames. No component of IRS 16 is coincident with Sgr A*. These data preclude the presence of a massive ($>10^6\ M_\odot$) black hole at the galactic centre. Any black hole present has a mass nearer to $100\ M_\odot$.*

EVIDENCE for a black hole at the galactic centre has been discussed by Brown and Liszt[1] and is summarized here. The primary evidence is the presence of a compact radio source, Sgr A*, first described by Balick and Brown[2]. Its linear size is <20 AU (ref. 3) whilst its radio luminosity, 2×10^{34} erg s^{-1}, is many orders of magnitude greater than that of any pulsar. Within the Galaxy, Sgr A* is unique. Probably coincident with it is a soft X-ray source similar to those in active galactic nuclei but emitting only 10^{35} erg s^{-1}. Moreover, within 4° of the centre is an extraordinary, variable source emitting the positronium annihilation line at 0.5 MeV (ref. 4).

Around Sgr A* is a striking radio continuum structure—the 'mini-spiral' of Ekers *et al.*[5]—which suggests special kinematic activity, either mass ejection[1] or accretion of small clouds onto a compact mass[6]. The inner region is largely free from dust, but far-infrared maps[7] indicate a ring of dust of inner radius about 1 pc which may coincide with portions of the mini-spiral. This dust is heated by a central source of radiation with a total optical/ultraviolet luminosity $\sim10^{40}$ erg s^{-1} and a temperature <35,000 K (ref. 8).

At spatial resolutions of 1-2 arc s, attention is focused on the near-infrared source IRS 16 (ref. 9), which lies very close to Sgr A*. Near IRS 16, emission lines of H and He I include a broad component[10,11] of velocity width 1,500 km s^{-1}. Assuming virial equilibrium, the dynamical mass near IRS 16 is thus $10^7\ M_\odot$. IRS 16 has been resolved[12] into three merged components aligned roughly along the galactic equator.

It has been recognized for many years[13] that the near-infrared emission from the central region of the Galaxy traces the stellar density distribution. The implied distribution approximates $r^{-1.8}$ over the range $0.1<r<40$ pc (refs 14, 15). Because the exponent is tantalizingly close to that predicted for the cusp around a black hole, it is tempting to identify IRS 16 with the bright central region of the cusp. If a massive black hole is present, we therefore expect a spatial coincidence between Sgr A* and one component of IRS 16.

As a test of the coincidence, astrometry of IRS 16 has been performed relative to a system of optical standard stars. Sgr A* is also located relative to the same reference frame of standard stars through a number of compact radio sources with optical counterparts. The accumulated uncertainty in the infrared-radio astrometry is estimated to be 0.5 arc s. The two determinations[12,16] suggest that IRS 16 centre coincides with Sgr A*, although the radio source appears displaced westwards according to the data of ref. 12.

A second, potentially more accurate, technique is that of directly comparing the radio and infrared maps and positioning them by common features. The first such comparison was made

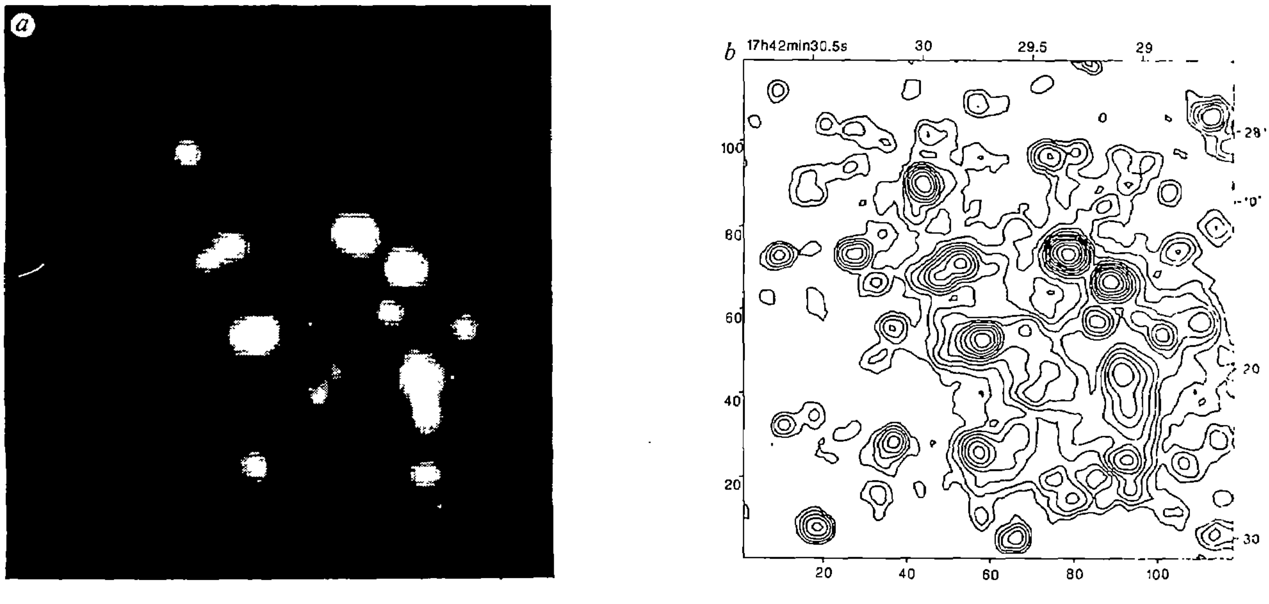

Fig. 1 *a*, The galactic centre at 3.8 μm; image made on 11 July 1984. The image measures 29.5 arc s on a side. IRS numbers are given for some sources. North is up and east to the left on this and all subsequent images. IRS 16 is the complex of sources to the west of IRS 1W. *b*, The same image in contour form. Contours are separated by 0.5 stellar magnitudes. A point source of 3.8 μm (L') magnitude 4.5 will just reach the highest contour; one of magnitude 9.5 the lowest plotted.

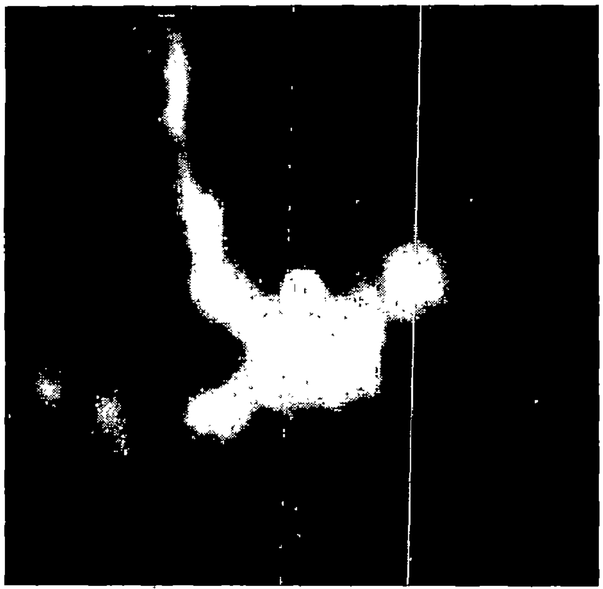

Fig. 2 A reproduction of the 6-cm data of Lo and Claussen[6]. Crosses mark the centres of the compact infrared sources as found by the best fit of the infrared data.

by Ekers[17], who used a published map of Br γ emission[12] to conclude that Sgr A* lies about 1 arc s west of every component of IRS 16.

We present an improved comparison of the radio and infrared maps of the galactic centre using new data at 3.8 and 4.8 μm. In agreement with Ekers, we find that Sgr A* does not correspond to the bright components of IRS 16.

Infrared data and radio structure

At short wavelengths, the galactic centre region is dominated by highly reddened stars and IRS 16 is a prominent object[9,18]. At longer wavelengths the pattern of radiation approaches that of the thermal radio, but IRS 16 cannot be detected. To make a direct comparison with the radio, we made a deep image of the region at 3.8 μm. Data described by Storey and Allen[12] have demonstrated that IRS 16 has identical structure at 1.6, 2.2 and 3.8 μm (a colour composite of the three was constructed and reproduced in ref. 19).The new image is reproduced in Fig. 1. We used the 3.9-m Anglo-Australian Telescope, with the infrared photometer-spectrometer operated in its imaging mode. At the focal plane a 1-arc s circular aperture was used; the seeing did not appreciably degrade the resolution. The image was sampled every 0.5 arc s, and in constructing Fig. 1 we have expanded the data to 0.25 arc s pixels by linear interpolation. Four separate images were combined into Fig. 1, allowing us to assess the internal positional accuracy as better than 0.15 arc s.

For the comparison with the radio data, we used the image at 6 cm made by Lo and Claussen[6]. This image (Fig. 2) also has a spatial resolution of about 1 arc s. It was sent in digital form to permit manipulations of the two images using Starlink software on the AAO VAX 11/780.

On the 3.8-μm image, the density of point sources is high. Some of them have not been recorded at other wavelengths. Most lack radio counterparts, but several diffuse patches of emission do correspond well with the radio map, and there is undoubtedly a strong correlation in the vicinity of IRS 2/13, on which we place much reliance. Nonetheless, before a secure fit of the two images could be made, a map at a longer wavelength was necessary to locate the compact sources IRS 1W, 5 and 10 relative to the northeasterly arm of radio emission.

An image at 4.8 μm was secured at a later date. The observational configuration duplicated that of the 3.8-μm map, but poorer seeing degraded the spatial resolution. Figure 3 reproduces this image. The details resemble more closely those at 6 cm, but with local enhancements of intensity. IRS 2/13 remains prominent. IRS 1W, 5 and 10 are now seen to lie east of the radio structure. IRS 1W and 10 have weak counterparts in the radio, whilst IRS 5 barely contacts the radio contours. Their locations strongly suggest a relationship with the mini-spiral. Presumably, they are single or multiple stars close enough to the gas clouds to cause local heating of the dust. Their displacement from the ionized gas is itself an interesting matter not addressed here.

With the help of the 4.8-μm image we located the 3.8-μm and 6-cm images with a relative uncertainty little more than 1 pixel or 0.25 arc s. Sgr A* was then found to lie significantly to the west of all components of IRS 16. Attempts to overlay the images with Sgr A* superimposed on any component of IRS 16 do not permit satisfactory registration of the infrared and radio sources.

IRS 16 in detail

Our attention turned to the region west of IRS 16. A small strip image was made at 2.2 μm (K) using a focal-plane diaphragm of 0.7 arc s diameter. Seeing at that wavelength was mostly below 0.5 arc s at the time. Several images were made, but only those with consistently good seeing were combined to create Fig. 4, which has almost double the spatial resolution of previous data[12]. The strip map includes IRS 7, and some faint point sources to the south. IRS 16 NE is bisected at the left edge of the image.

IRS 16 SW and centre are now seen to be discrete sources extended on the scale of about 1 arc s. A previously ignored component, IRS 16 NW, is unresolved, and for this reason appears as intense as the peak of SW and centre. Faint emission is seen west of IRS 16 centre, at the location of Sgr A*. Adopting $K=6.7$ for IRS 7, the various components of IRS 16 peak at about 10.0 mag in the 0.7-arc s beam. The sources at the location of Sgr A* has $K=11.4$. Both of these numbers have been corrected from the raw data for the fact that the darkest part of Fig. 4 (relative to which the photometry is performed) lie above the dark sky level on the data of ref. 12.

We now examine the impact of these observations on models invoking a massive black hole at the site of Sgr A*.

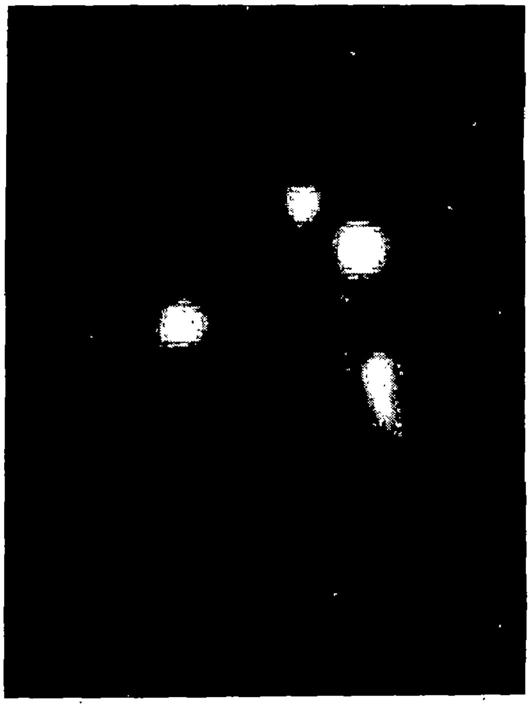

Fig. 3 4.8-μm image (8 November 1984). Although inferior to Figs 1 and 2, features of both these images can be seen.

IRS 16 as the cusp core

We adopt the popular assumption that Sgr A* is a 10^6–10^7 $M_\odot$ black hole. We first ask whether the observed structure of IRS 16 is consistent with this complex source being the core of a cusp around the black hole.

A point mass in an extended distribution of stars dominates the gravitational potential within the classical accretion radius (r_a):

$$r_a = \frac{2GM_h}{v_s^2} = \frac{M_h}{5\times10^6\,M_\odot}\left[\frac{225\text{ km s}^{-1}}{v_s}\right)^2 \text{pc} \sim 20\text{ arc s} \qquad (1)$$

where M_h is the mass of the object, and v_s is the stellar velocity dispersion. Due to energy diffusion, a cusp in the stellar density distribution of the form $\rho \propto r^{-1.75}$ will develop[20,21] within r_a on a timescale longer than the initial two-body relaxation time[22]:

$$t_R = \frac{\sqrt{2}\,v_s^3}{\pi G^2 M_*^2 n \ln(0.5N)} \qquad (2)$$

in a stellar system with a mean stellar mass M_*, a stellar density of n, and a total number of stars N. The inferred properties of the inner 1 pc of the galactic nucleus ($n \sim 4\times10^5\text{ pc}^{-3}$, $v_s \sim$ 200–300 km s^{-1})[14] imply that $t_R \sim 10^{11}$ yr at the present epoch. However, even without energy diffusion, the adiabatic growth of a black hole produces a cusp in the stellar density[23] of the form $r^{-1.5}$. Therefore, the formation of a cusp around such a hypothetical black hole in the galactic centre would seem inevitable.

The observed density index in the central parsec of the Galaxy is −1.8, consistent with that of an energy diffusion cusp. Using existing data[14,15], the integrated magnitude at K within a circular aperture of radius r is $m(r) = 8.5 - 3\log(r)$. Within the 0.7-arc s aperture of the present observation, we should therefore expect $K = 9.9$, consistent with any of the IRS 16 components, but 1.5 mag brighter than found at the location of Sgr A*.

Can the hole migrate away from the centre of its cusp due to interactions with cusp stars[24]? Although the hole may deviate from the centre-of-mass of the hole-cusp system, it cannot deviate significantly from the position of maximum brightness of the cusp. The innermost, tightly bound stars will follow the hole on its brownian motion resulting from interactions with more distant cusp stars. The only possible deviation of the hole from the point of maximum brightness can be due to statistical fluctuations in the space density of cusp stars, and this does not become significant except at radii within which there are only about 10 cusp stars, in this case 10^{-5} pc. We find a displacement of Sgr A* from the IRS 16 components of >1,000 times this limit, implying that none of the bright IRS 16 components can be the core of a hypothetical cusp.

Association of young stars

The fact that Sgr A* does not coincide with any of the bright components of IRS 16 implies that a possible black hole associated with this object does not emit significantly at 2.2 μm. If we characterize the radiation from the hole's accretion disk by a black body, we have an upper limit to its temperature of 35,000 K from the presence of Ne II (ref. 8). To provide the optical and ultraviolet energy seen to be heating the dust requires a K magnitude of about 8, which is clearly precluded. This is a lower bound to K for any reasonable energy distribution other than line emission. Thus no object associated with Sgr A* provides the bulk of the luminosity of the galactic centre. The observed K magnitude of 11.4 implies an upper limit to the luminosity of about 10^{39} erg s^{-1}, which is compatible with the low level of radio and X-ray activity, and with the presence of an inactive, massive black hole there. But then, what is the source of ionizing radiation at the galactic centre?

There are many discrete sources in the galactic centre region which must contain stars of significant luminosity. The differences between the infrared and radio continua alone indicate this fact. The discrete infrared sources can be interpreted either as local centres of heating[25] or as external heating of local density enhancements[26]. Most of these sources appear to suffer local extinction from the dust that re-radiates at long wavelength; they cannot illuminate the dust ring 2 pc from the centre because it is transparent to their radiation. We should seek the required luminosity in the bluer infrared sources. IRS 16 is the brightest of these.

Geballe *et al.*[11] demonstrated that IRS 16 (loosely defined within a 4-arc s beam) is responsible for most of the ionization within the central parsec. Its integrated K magnitude is about 8, so if the constituent stars approach 35,000 K in temperature, they alone can account for the required luminosity. The concentration of M supergiants near the galactic centre may be explained by a burst of star formation which occurred in the nuclear region $\sim10^7$ yr ago[27,28]. Such a burst would leave at least one concentration of B stars now. We therefore regard all the components of IRS 16 as clusters of hot stars, remnants of the last starburst. If their mean spectral type is B0, about 100 are required, or roughly 25 in each of the four major components. The clumpy, irregular appearance of these components is better explained in this way than as the more symmetrical cusp or compact accretion disk associated with an active black hole.

However, the proximity of these objects to the point radio source severely constrains the mass of the black hole. If, as we suggest, the sources are unbound clumps of B stars, then they will disperse on a timescale roughly comparable to the orbit time about the black hole, or

$$t_D \sim 2\left(\frac{GM_h}{r_0^3}\right)^{-1/2} \sim 500\left(\frac{M_h}{5\times10^6\,M_\odot}\right)^{-1/2} \text{yr} \qquad (3)$$

where $r_0 \sim 0.1$ pc is the typical projected distance of the clumps from the hole. The probability of observing two or three such

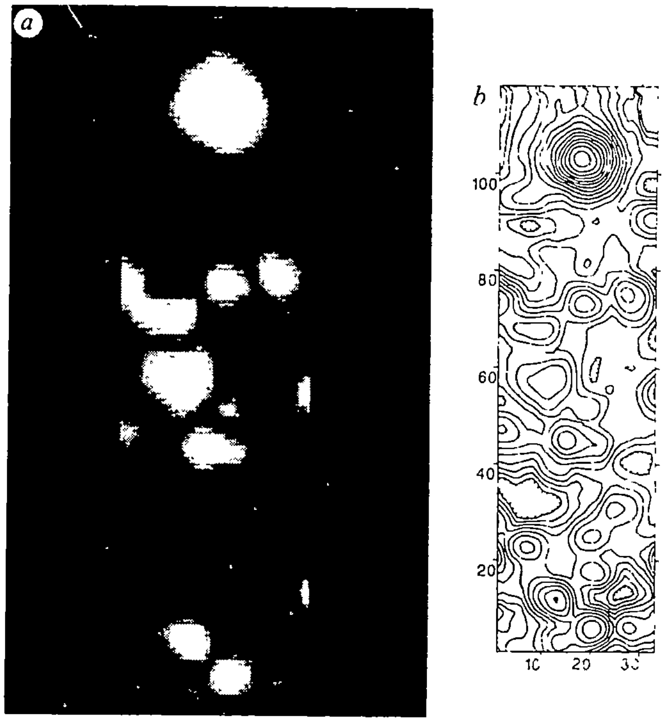

Fig. 4 *a*, Strip image at 2.2 μm through IRS 7 and 16. The image measures 5.0 × 17.7 arc s and the pixels are 0.15 arc s square. The spatial resolution, about 0.8 arc s, is a factor of two higher than any previous data. The IRS sources are identified and Sgr A* is marked by a cross of dimension 0.5 arc s^{-1}, the 2σ uncertainty in its position. *b*, The same image in contour form. The contours are separated by 0.5 stellar magnitude and range between 6.5 and 14.0 in K magnitude.

clumps in the central 0.1 pc is extremely low unless star formation is occurring continuously. For any likely initial mass function, this is precluded by the cool radiation field of the region. Moreover, the tidal field of a massive black hole would require implausibly dense protostellar clouds:

$$\rho > \frac{6M_h}{r_0^3} \sim 7\times10^{-13}\frac{M_h}{5\times10^6\,M_\odot}\,\mathrm{g\,cm^{-3}} \qquad (4)$$

What alternative interpretations of the IRS 16 sources are possible?

(1) They are background or foreground sources seen in projection within 2 arc s of the black hole. Not only would it be highly fortuitous that the only blue objects seen in the inner 2 pc apparently lie so close to the centre, but we should have to find another source of luminosity to power the far-infrared emission.

(2) The clumps are dense gravitationally bound subclusters. It has been suggested[29] that globular clusters will be dragged into the centre of a galaxy by dynamical friction. Again, to prevent tidal disruption, their mean density must be given by equation (4). This corresponds to a stellar density in the subcluster of almost $10^{10}\,M_\odot\,\mathrm{pc}^{-3}$ within 0.02 pc. Certainly, no presently observed globular cluster cores have these properties; in the most dense globulars $n \sim 10^5\,M_\odot\,\mathrm{pc}^{-3}$ (ref. 30).

The clumps could be the highly evolved cores of old, massive globular clusters. But the present stellar relaxation time in such systems is only $\sim10^7$ yr. Because the lifetime of such a cluster is no more than 30 t_R (ref. 31), to see several of them they would have to be replaced or reformed every 10^8 yr. External replacement over 10^{10} yr would have produced an unacceptably large mass in the central 0.1 pc of the Galaxy, exceeding $3\times10^7\,M_\odot$.

(3) Several massive black holes occupy the central regions, each with its own cusp of bound stars. Such a configuration is dynamically unstable[32], leading to the formation of at most a binary system. Nor does it explain the uniqueness of Sgr A*.

(4) The bright components are one or more background stars in the Galaxy which have been gravitationally imaged by the massive black hole. The required amplification factor, 10^5–10^6, implies that the star lies within 4×10^{-5} arc s of the direction of the black hole. Given the mean density of stars along a line-of-sight through the Galactic plane, the probability of this is $\sim10^{-7}$.

A low-mass black hole

We have attempted to reconcile the observations with the existence of a black hole coincident with Sgr A* and of mass exceeding $10^6\,M_\odot$ and have failed to do so. Our conclusion, which we now justify, is that the black hole within Sgr A* is no more massive than about 100 $M_\odot$.

This alternative does not contradict the great body of observational material. None of the phenomena noted above requires a black hole more massive than 100 $M_\odot$. Suggestions[33] that the kinematic evidence requires a point mass $>10^6\,M_\odot$ assume that the gas motions within 0.5 pc of the centre are virialized and thus trace the gravitational potential. This need not be the case; indeed, the broad emission lines seen in the direction of IRS 16 may be high-velocity outflow from the region of a low-mass black hole (as suggested in ref. 11). The fact that the central ionization source can be attributed to the clumps of B0 stars identified with IRS 16 removes the justification for a more bizarre source. Moreover, the most straightforward interpretation[34] of the positronium annihilation line implies a black hole of mass no more than a few hundred $M_\odot$.

The similarity of the stellar density distribution in the inner parsec to that in a cusp around a massive black hole is not compelling: the density law also resembles an isothermal sphere (r^{-2}) with a small (0.1 pc) core and a central density $>10^7\,M_\odot\,\mathrm{pc}^{-3}$. The two-body relaxation time in that core would be 2×10^9 yr and the stellar collision time would be 9×10^9 yr. As the timescale for dynamical evolution is the smaller of t_{coll} and 20–30 t_R, the structure need change very little over the age of the Universe.

The dispersal of unbound groups of young stars would be considerably less rapid in this case. In a constant-density or 'harmonic' case, where all orbit periods are equal, structure would never disappear. It is unrealistic to assume that the IRS 16 associations lie in a pure harmonic oscillator potential; a 5–10% variation in the density of the underlying isothermal core would cause dispersal by phase mixing in 10–20 orbit times, or about 10^4 yr. Moreover, if $M_h < 5\times10^4\,M_\odot$, the Roche limit constraint (equation (4)) is relaxed and the associations could be gravitationally bound subclusters of no more than 1,000 $M_\odot$. Thus the existence of associations or clusters of young stars, as evidenced by the structure in IRS 16, is only plausible if the mass of the hole is considerably less than the mass of the isothermal core, that is, $M_h < 10^5\,M_\odot$.

Determination of the velocities of the IRS 16 components would verify (or falsify) our claim that the black hole is much less massive than $10^6\,M_\odot$. For a massive black hole, the IRS 16 components should have a velocity $>450\,\mathrm{km\,s^{-1}}$. This could be detected in the radial velocity of the associated Br γ line.

The arguments we have given do not tightly constrain the mass of the black hole. However, consideration of the growth rate of a black hole in the stellar density of the galactic centre make it unlikely that the mass is as high as 1,000 $M_\odot$; such a black hole would consume the galactic core, thus growing to a mass of 10^6–$10^7\,M_\odot$ in 10^9 yr (refs 35, 36). The upper bound to the luminosity of Sgr A* is about that of a 100 $M_\odot$ black hole accreting at the Eddington luminosity. Therefore, we conclude that the central parsec of the Galaxy comprises an isothermal sphere of stars having a core radius ~0.1 pc and central density $>10^7\,M_\odot\,\mathrm{pc}^{-3}$, a few small associations or clusters of newly formed B stars within that core, and an accreting black hole of mass $\leq 100\,M_\odot$.

Estimates derived from satellite data of photosynthetically active radiation absorbed by terrestrial vegetation correlate with atmospheric carbon dioxide concentrations measured at surface recording stations, suggesting that satellite data can be used to estimate terrestrial photosynthesis.

TERRESTRIAL photosynthesis is inversely related to atmospheric carbon dioxide concentrations and is an important component of the global carbon cycle. The lack of temporal resolution and global data has prevented comparisons between estimates of terrestrial photosynthesis and measurements of atmospheric CO_2 concentrations from remote maritime monitoring stations. This is now possible using data derived from meteorological satellites.

Primary production

The biosphere absorbs CO_2 from the atmosphere through photosynthesis which incorporates absorbed carbon into carbohydrates, giving off O_2. In the terrestrial biosphere, CO_2 absorption occurs in the green leaves of plants, where intercepted photosynthetically active radiation (IPAR) (0.4–0.7 μm) is absorbed by the photosynthetic pigments. The energy of the absorbed photons is used to drive the reaction of photosynthesis, yielding carbohydrates through primary production. Incident radiation in the 0.4–0.7-μm region is strongly absorbed by green leaves (by scattering and absorption by photosynthetic pigments), and radiation in the 0.7–1.1-μm region is strongly backscattered or reflected (by scattering in the absence of absorption)[1-5]. Thus, reflected radiance from the red and near-infrared spectral regions can be used to estimate the green-leaf biomass of plant canopies[6,7], are directly be related to the IPAR[8-13], the photosynthetic capacity and the resistance to water-vapour transfer of plant canopies[13].

Atmospheric CO_2

Measurements of atmospheric CO_2 concentrations at monitoring stations have a seasonal oscillation superimposed on an annually increasing trend. The annual amplitude of this oscillation is ~15 parts per 10^6 (p.p.m.) at Point Barrow, Alaska, and decreases southward to ~6 p.p.m. at Mauna Loa, Hawaii, and to ~1–2 p.p.m. in the Southern Hemisphere. The annual maximum atmospheric CO_2 concentration in the Northern Hemisphere occurs in the late spring or early summer and the annual minimum concentration occurs in the autumn[14,15]. The annual oscillation of atmospheric CO_2 is due primarily to seasonal exchange of CO_2 with the terrestrial biosphere[14,16,17]; in contrast, there is little seasonal exchange of CO_2 with the upper ocean[18,19]. The CO_2 exchange with the biosphere has been simulated using diffusion, advection-diffusion, three-dimensional tracer models[20-22] and biospheric-exchange functions. Bolin and Keeling[23] and Pearman and Hyson[24] derived CO_2 sources and sinks consistent with atmospheric CO_2 observations, while Azevedo[25] constructed simple biospheric-exchange functions based on assumed vegetation seasonality and geographical location. However, the biospheric CO_2 drawdown and release functions that correlated best with measured CO_2 concentrations showed differences by at least a factor of 2 (refs 20–25). The release of CO_2 from terrestrial vegetation can be approximated if primary production and the temperature regime are known; the drawdown of CO_2 by terrestrial vegetation can be determined if primary production is known. Thus, elucidation of the role of the terrestrial biota in the gobal carbon cycle requires an estimate of the terrestrial primary production; this can be achieved through remote sensing by satellite.

Remote sensing

By monitoring global changes in the IPAR of the terrestrial biota, an estimate of CO_2 drawdown and primary production can be obtained through the relationships between leaf structure, leaf density and light in plant canopies, and that between IPAR and photosynthetic capacity[13].

The CO_2 cycle involves not only photosynthesis and respiration, but also decomposition of carbon compounds, uptake and release by oceans, combustion of fossil fuels, and fires involving vegetation. Deforestation contributes towards atmospheric CO_2 through burning and/or subsequent decomposition of phytomass, litter and associated carbon concentrations in the soil, although the magnitude of this contribution is uncertain[26,27]. Remote sensing by satellite enables the temporal and spatial variations in the IPAR of the terrestrial biota to be quantified.

Remote-sensing studies of the biota have used Landsat and meteorological satellites data. Landsat multispectral scanner (MSS) data, with a spatial resolution of 80 m, are not appropriate for the study of seasonal changes in the terrestrial biota, because ~5,000 Landat MSS scenes would be required to cover the world's surface. The polar-orbiting meteorological satellites of the National Oceanic and Atmospheric Administration (NOAA) are suitable for observing terrestrial IPAR dynamics. The advanced very-high-resolution radiometer (AVHRR) sensor on board these polar-orbiting satellites daily collects global radiance data at a 4-km spatial resolution. Combinations of channel 1 (0.55–0.68 μm) and channel 2 (0.73–1.1 μm) data from the NOAA satellites' AVHRR have been used to study continental land cover, global vegetation phenology and net primary production by grasslands using data from 1 to 4-yr periods[28-31].

Data methods and use

Data on monthly atmospheric CO_2 concentrations for 1982–84 were obtained for Point Barrow, Alaska (147° W, 71° N), and

---

§ Present address: NOAA/PMEL, Seattle, Washington 98115, USA.

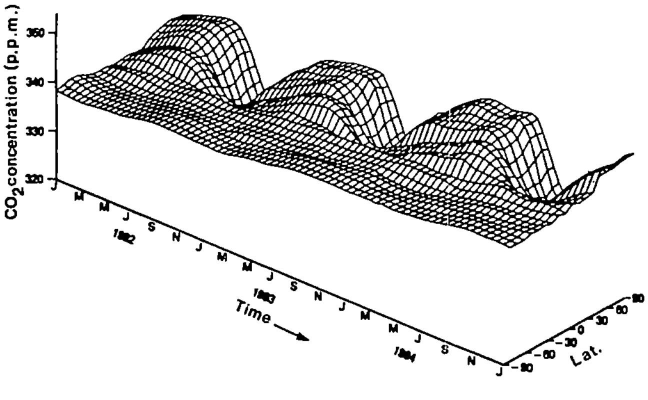

Fig. 1 Variation of global atmospheric CO_2 concentrations with latitude and time based on the NOAA/GMCC flask measurements for 1982–84.

Mauna Loa, Hawaii (156° W, 20° N); and from January 1982 to September 1984 for the South Pole (90° S). Stations there are operated by the NOAA Geophysical Monitoring for Climatic Change (GMCC) programme, and the CO_2 flask samples are analysed at the Scripps Institute of Oceanography. CO_2 concentrations for 20 globally dispersed monitoring sites operated and analysed by NOAA/GMCC for 1982–84 were also obtained.

The atmospheric CO_2 concentration is the combined response to terrestrial biospheric, oceanic and anthropogenic sources and sinks, convolved with long-range transport. Figure 1 shows the total CO_2 signal from January 1982 to December 1984 measured at the 20 global monitoring stations. An annually increasing trend of ~1.5 p.p.m. yr^{-1} from anthropogenic sources, and an annual cycle, with an amplitude greatest around 50°–70° N, is evident. To extract the seasonal variation from the CO_2 records, we computed the 12-month running means for each station and subtracted these from the CO_2 record (see ref. 15).

Global weekly data from NOAA-7's AVHRR were obtained for the period from 12 April 1982 to 28 October 1984 (ref. 32). These data were re-mapped from a polar stereographic projection to a Mercator projection so that the world could be represented in a single image. The normalized difference vegetation index (NDVI) $[(C_2-C_1)/(C_2+C_1)]$ was calculated[6,7], and the highest monthly NDVI value was selected from the weekly data for each month between April 1982 and October 1984 (Table 1). This procedure minimizes the effects of Sun angle, off-nadir viewing, atmospheric pathlength and aerosols, and clouds, all of which decrease the NDVI[33]. In winter conditions, spurious NDVI values result from a combination of low solar illumination levels, differing dark-current levels in channels 1 and 2, and pathlength-associated variation in atmospheric effects. These effects are apparent not only during the respective hemisphere winters, but also if the NDVI is calculated from AVHRR data acquired during the night. To compensate for these spurious values, mean monthly surface temperature data were acquired[34], and areas within the 0 °C or colder regions were assigned NDVI values of 0.00 because physiological evidence suggests that the rate of photosynthesis at 0 °C is close to zero[35].

The monthly NDVI data, which have an average grid-cell size of ~40 km, were used to compute average values for global latitude zones. The zonal averages were multiplied by the land area within each zone (to weight the averages by the land area involved) and summed for various latitude zones; the sum for each larger zone was then divided by the total land area in that zone. The NDVI for a latitude zone represents the potential IPAR; hence, we have assumed that the NDVI is directly related

Table 1 Weekly data used for monthly NDVI composite images

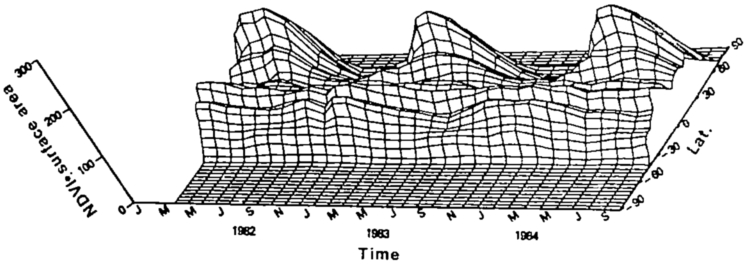
The maximum monthly value was selected from the weekly data.

Fig. 2 Weighted NDVI data plotted against time and latitude zone. Note the highly seasonal effects in the northern latitudes, the influence of deserts in the 20°-30° N latitude zone, the generally constant response in equatorial areas, and the influence of the low proportion of land area south of 30° S. See also Fig. 1. The average NDVI value for each 5° latitude zone has been multiplied by the land area in the zone to compensate for global variations in land area.



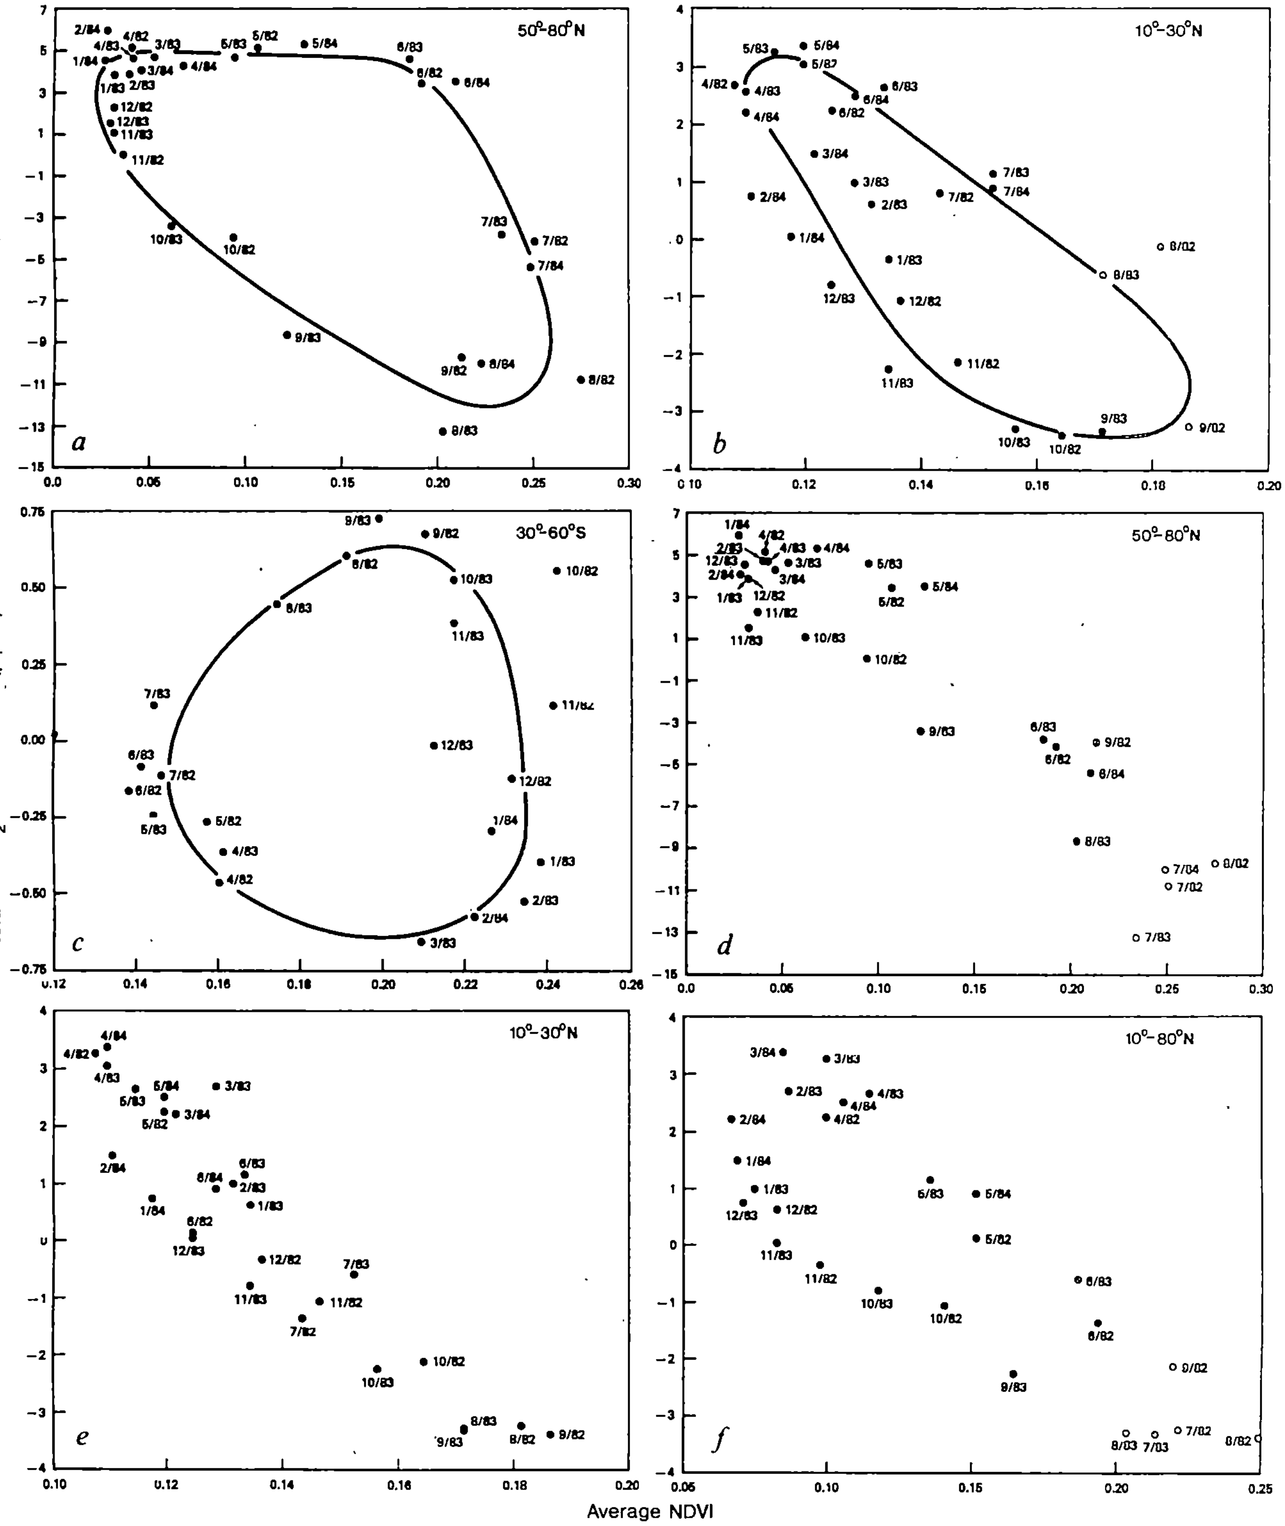


Fig. 3 Relationships between atmospheric CO_2 concentrations and NDVI averages with and without time lags between NDVI measurements and CO_2 measurements. The CO_2 data are from stations at Point Barrow, Alaska: *a*, no time lag; *d*, 1-month lag; Mauna Loa, Hawaii: *b*, no time lag; *e*, 1-month lag; *f*, 2-month lag; South Pole: *c*, no time lag. The corresponding NDVI averages are from 50° to 80° N for Point Barrow, 10° to 30° N and 10° to 80° N for Mauna Loa, and 30° to 60° S for the South Pole.

to the photosynthetic capacity[13] of the terrestrial surface in that zone and should be inversely related to atmospheric CO_2 concentrations. Figure 2 shows the latitudinal and temporal variation of the zonally averaged NDVI (weighted by land area) from April 1982 to October 1984. Consistent with considerations of growing seasons, the maximum zonally averaged and weighted NDVI occurs in summer at middle to high latitudes in the Northern Hemisphere. This pattern is a consequence both of the large proportion of land area and the highly seasonal behaviour of vegetation at these latitudes. The Southern Hemisphere south of 30° S has a low weighted NDVI because its vegetation is not as seasonal and the proportion of land area is less than in latitude zones north of 30° S. The weighted NDVI in equatorial areas is high throughout the year, and a desert belt is apparent as a depressed weighted NDVI from ~20° N to ~30° N. Figure 2 also shows differences in the weighted NDVI from 1982 to 1984. The 1982 global peak occurred in August, whereas the 1983 and 1984 global peaks occurred in July.

Results

The data presented in Figs 1 and 2 reveal an inverse relationship between the NDVI and the seasonal variations in atmospheric CO_2: in the Northern Hemisphere, the NDVI increased in spring to summer as the atmospheric CO_2 concentration decreased.

The NDVI data were plotted against the atmospheric CO_2 data from the Point Barrow, Mauna Loa and South Pole stations (Fig. 3). The South Pole data (Fig. 3*c*) showed no relationship between NDVI and CO_2: south of 30° S, the oceanic area is greater than land area which leads to smaller land/sea contrasts in air temperature. Consequently, seasonal behaviour of both the NDVI and the atmospheric CO_2 concentrations is less marked than in corresponding latitudes of the Northern Hemisphere (Figs 1, 2). Remote sources of CO_2 may also dominate or obscure local sources of CO_2 through atmospheric circulation and mixing in this region.

In contrast, the CO_2 data from Point Barrow and Mauna Loa and the NDVI data from 50 to 80° N and from 10 to 30° N, respectively (Figs 3*a*, *b*), showed a circular/elliptical relationship. At Point Barrow, the data showed no change in relative CO_2 concentration from April to June of 1982, 1983 and 1984, while the NDVI from 50 to 80° N increased (Fig. 3*a*). At Mauna Loa, however, the data showed a decrease in relative CO_2 concentration from May to June of 1982 and 1983, while the NDVI from 10 to 30° N again increased (Fig. 3*b*).

The Point Barrow results are consistent with heterotrophic respiration rates reported for soil and litter in the tundra and taiga zones between April and June[36,37]. As soon as the ground thaws, soil and litter respiration releases a burst of CO_2 and this could explain the April to June displacement of the relative CO_2-NDVI relationship in Fig. 3*a*.

Atmospheric circulation and boundary-level mixing effects would be expected to delay equilibration of CO_2 concentrations by several weeks. A time lag between the NDVI and the measured atmospheric CO_2 concentrations would be expected because of the distance between the Point Barrow and Mauna Loa stations and mid-latitude forest sites which have maximum seasonality in photosynthesis. When the NDVI for month n was plotted against the atmospheric CO_2 concentration for month $n+1$, approximately linear relationships were found with the Point Barrow and Mauna Loa data (Fig. 3*d*, *e*). The negative slopes in Fig. 3*d* and *e* indicate the increased absorption of CO_2 by increased amounts of terrestrial photosynthetic activity.

Inverse linear relationships, found between the Mauna Loa CO_2 concentrations, lagged by 2 months, and the NDVI for 10–80° N (Fig. 3*f*) showed that CO_2 oscillations at Mauna Loa represented the CO_2 response to the seasonal vegetation dynamics of the Northern Hemisphere and were not dominated by proximate sources and sinks. In addition, the globally averaged CO_2 cycle has a peak-to-peak amplitude of 4–5 p.p.m., about 75% of that at Mauna Loa, and is nearly in phase with the cycle there. The annual cycle at Mauna Loa is thus characteristic of the globally averaged cycle.

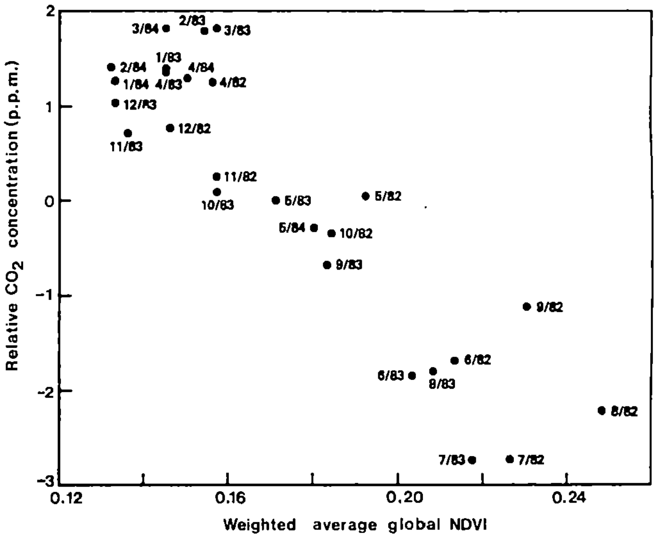

Fig. 4 The globally averaged atmospheric CO_2 concentration plotted against the globally averaged NDVI with a time lag of 1 month. The CO_2 data are from the global network of 20 NOAA/GMCC stations.

Figure 4 shows the globally averaged CO_2 measurements from the 20 stations plotted against the globally averaged NDVI. When a lag of 1 month was introduced into the CO_2 data, an inverse linear relationship was found, suggesting that the global NDVI represents the photosynthetic capacity of the terrestrial biosphere.

Conclusions

Our data show the relationship between monthly variations in atmospheric CO_2 concentrations and terrestrial NDVI dynamics, which are, in turn, estimates of IPAR and photosynthetic capacity. Note that we have not considered factors such as respiration, decomposition, consumption of fossil fuels, oceanic processes and burning of vegetation, all of which influence atmospheric CO_2 concentrations. Our analysis demonstrates the measurable link between atmospheric CO_2 drawdown and terrestrial NDVI dynamics and suggests that there may be quantitative relationships between multi-temporal satellite data and atmospheric CO_2 drawdown. The inclusion of oceanic CO_2 uptake and release, respiration and decomposition processes, fossil fuel contributions and other CO_2 sources and sinks can be used to advance our quantitative understanding of the global CO_2 cycle.

Solvation energy in protein folding and binding

David Eisenberg & Andrew D. McLachlan*

We have developed a method for calculating the stability in water of protein structures, starting from their atomic coordinates. The contribution of each protein atom to the solvation free energy is estimated as the product of the accessibility of the atom to solvent and its atomic solvation parameter. Applications of the method include estimates of the relative stability of different protein conformations, estimates of the free energy of binding of ligands to proteins and atomic-level descriptions of hydrophobicity and amphiphilicity.

OF the forces that guide a polypeptide chain to its folded form in water, solvent interactions, including the hydrophobic interaction, are thought to be among the most important[1–4]. Yet these interactions are currently evaluated by relatively primitive methods. This is in contrast to the other component energies that stabilize proteins, such as hydrogen bonds, for which atom-atom potential functions have been devised[5–7]. Present methods for estimating the contribution of solvation energy to protein stability include the assumption that the hydrophobic character of each amino-acid residue can be summarized by a single number, the amino-acid hydrophobicity[8–12]. This is an oversimplification for amino acids such as Trp, Tyr, Glu, Gln, Lys and Arg which have both polar and apolar parts. Some authors have tried to overcome this limitation by devising more elaborate residue hydrophobicities to improve the description[8,13,14]. Also an oversimplification is the commonly used approximation that the hydrophobic energy of a folded protein molecule is proportional to the total protein surface that is accessible to water, regardless of whether the exposed surface is apolar, polar or charged[15].

To develop an explicitly atomic description of the interaction of water with a protein, we extend the ideas of Langmuir[16], Cohn and Edsall[17], and others[18,19]. The basic assumption is that the free energy of interaction of a solute with water can be considered as a sum of energies of atomic groups. We follow Langmuir in using the exposed surface areas of a group as a measure of its interaction with solvent. In practice we use the solvent-accessible surface area of Lee and Richards[20] and other recent workers[21–24]. This is defined as the area over which the centre of a water molecule of radius 1.4 Å can move while maintaining unobstructed contact with the group. In our method, the sign and strength of the water-solvent interaction are specified by the atomic solvation parameter (ASP) of each atom accessible to water. These values are determined, as described below, from free energies of transfer[8–12]. Thus, our method effectively combines two common approaches for evaluating hydrophobic forces: computation of solvent-accessible surface areas; and estimating energies from free energies of transfer. Our method, however, extends the first approach by weighting the effect of each atom by its polar or apolar character, and extends the second in permitting calculation of the solvation energy from the coordinates of individual atoms in each residue. It advances both methods in permitting estimates of the free energy of transfer of small molecules and of the contribution of solvation to the free energy of binding of small molecules to proteins.

Atomic contributions

Here we express the contribution of protein-solvent interactions to the free energy of protein folding as a sum over all atoms of the structure (except hydrogen atoms, which are not treated explicitly). The term for each atom is the product of its solvent-accessible area[20] and its ASP for transfer from the interior of a protein to aqueous solution. The transfer to solution of a single atom, i, immersed in protein is depicted in Fig. 1*a*. Let the accessible surface area of the atom be given by A_i, and its atomic solvation parameter be given by $\Delta\sigma_i$. Then the free energy of transfer (ΔG) is

$$\Delta G_i = \Delta\sigma_i A_i \qquad (1)$$

Now consider the transfer to water of amino-acid residue R immersed in protein (Fig. 1*a*). We assume that the change in free energy for this process can be approximated as a sum of atomic terms, each like that of equation (2)

$$\Delta G_R = \sum_{\text{atoms i}} \Delta\sigma_i A_i \qquad (2)$$

Note that the areas A_i now depend on the conformation of the amino acid, and that some atoms will be obscured by their

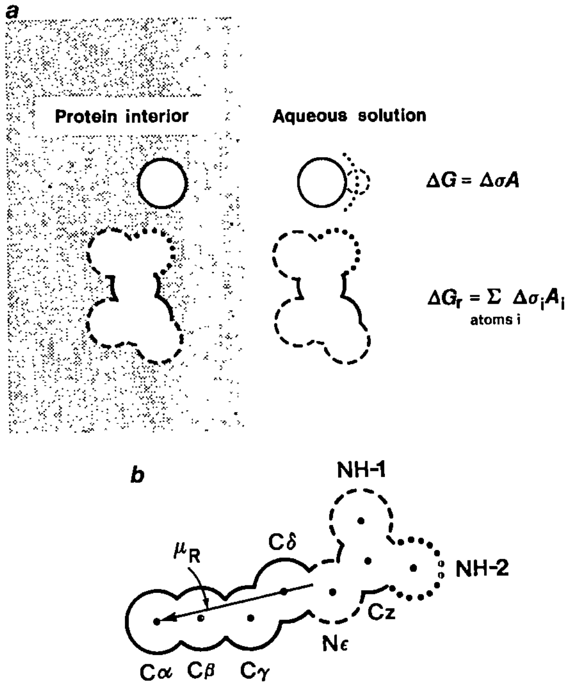

Fig. 1 *a*, Transfer of an atom and a molecule immersed in protein to water. The molecule contains three different types of atoms, represented by solid, dashed and dotted outlines. The definition of accessible surface area is illustrated for the atom at the right, where the centre of a sphere of radius 1.4 Å, tangent to the atom, sweeps out the accessible area. *b*, The atomic hydrophobic moment for the Arg side chain, shown as a vector running from the side-chain centre to the α-carbon atom. The chain takes the conformation specified in the CORELS[40] computer program dictionary. The dotted NH-2 atom is the most exposed nitrogen and is accordingly treated as the charged nitrogen.

neighbours. We assume that conformation is not significantly changed during transfer.

The validity of equation (2) can be tested by a fit to experimental free energies of transfer. For proteins the fit is carried out by considering atoms in five classes: carbon, neutral oxygen and nitrogen (N/O), charged oxygen (O^-), charged nitrogen (N^+) and sulphur. Then the free energies of the common amino acids can be represented by equations of the type

$$\begin{aligned}\Delta G_R = {} & \Delta\sigma(\mathrm{C}) \sum_{\mathrm{C\ atoms\ i}} A(\mathrm{C_i}, \mathrm{R}) \\ & + \Delta\sigma(\mathrm{N/O}) \sum_{\mathrm{N,\ O\ atoms\ i}} A(\mathrm{N/O_i}, \mathrm{R}) \\ & + \Delta\sigma(\mathrm{O^-}) \sum_{\mathrm{O^-\ atoms\ i}} A(\mathrm{O_i^-}, \mathrm{R}) \\ & + \Delta\sigma(\mathrm{N^+}) \sum_{\mathrm{N^+\ atoms\ i}} A(\mathrm{N_i^+}, \mathrm{R}) \\ & + \Delta\sigma(\mathrm{S}) \sum_{\mathrm{S\ atoms\ i}} A(\mathrm{S_i}, \mathrm{R}) \qquad (3)\end{aligned}$$

in which $\Delta\sigma(\mathrm{C})$ is the ASP for carbon and $A(C_i, \mathrm{R})$ is the solvent-accessible surface area of carbon atom i in a standard conformation[21] of residue R, and so forth for the other terms. The O^- term describes the charged oxygen atoms in Glu and Asp; the N^+ term describes the charged nitrogen atoms in Lys, Arg and His residues; the N/O term describes all uncharged N and O atoms. In Asp, Glu and Arg the most exposed N or O atom is taken to be the atom on which the charge is concentrated. Only certain terms of equation (3) are needed to describe any given residue. For example, Asn requires only C and N/O terms. The *p*H dependence of charges is ignored, an assumption that might be thought to be poor for His, but the solvent-accessible areas of the N atoms are not large.

Table 1 Amino-acid sovation free energies and group moments

Amino-acid residue	ΔG_{OBS}*	ΔG_R†	ΔG_{TAN}‡	μ_a§	cos θ
Gly	(0)	(0)	(0)	(0)	—
Ala	0.42	0.67	0.50	0	—

Arg	−1.37	−2.1	—	10.0	−0.96
Group		ΔG_{OBS}‖ (ref. 17)		ΔG_R# (equation (3))	
$-CH_2-$		0.67		0.56	
$-C_6H_5$		1.90		1.6	
-OH		−0.76		−0.66	
$-CH_2-CONH-$		−1.14		0.66	
Gly ionization		−3.7		−2.6	

Observed and calculated free energies of transfer are given in units of kcal mol^{-1}, calculated residue hydrophobic moments μ_a are given in kcal mol^{-1} Å. ΔG_{OBS} and ΔG_{TAN} are experimental free energies of transfer relative to glycine. ΔG_R is the calculated value; μ_a is the calculated residue hydrophobic moment; and θ is the angle between the direction of the residue hydrophobic moment and a line from the α-carbon nucleus to the geometric centre of each side chain.

* ΔG_{OBS} is the observed value of π reported by Fauchere and Pliska[25] multiplied by $2.30\,RT = 1.36$ kcal mol^{-1}; π(side chain) is defined as log *D*(acetyl amino-acid amide) − log *D*(acetyl glycine amide), where *D* is the distribution coefficient for octanol/water.

† Calculated from equation (3).

‡ Observed values for transfer from ethanol to water from ref. 9.

§ Atom-based hydrophobic moment, defined in equation (5), below, using solvent-accessible surface areas from ref. 21 and atomic coordinates from ref. 39. These moments depend on the detailed conformation of the side chain, but not sensitively, because the corresponding values based on the coordinate dictionary supplied with the computer program CORELS[40] differ by an average of only 3%.

‖ Experimental values from ref. 17 (from p. 212 except for the value for the -OH group which is from p. 206). Gly ionization is for the process: $NH_2\text{-}CH_2\text{-}COOH \rightarrow {}^+NH_3\text{-}CH_2\text{-}COO^-$.

# Calculated from equation (3) as follows: $-CH_2-$, using the average accessible are of 8 $-CH_2$ groups in 5 residues; Gly ionization from tabulated areas[21]; and the -OH group as $\Delta G_R(\mathrm{Ser}) - \Delta G_R(\mathrm{Ala})$ and $-C_6H_5-$ as $\Delta G_R(\mathrm{Phe})\text{-}G_R(\mathrm{Ala})$, corresponding to the experimental values[17].

¶ Both ΔG_{OBS} and ΔG_R refer to half-cystine. We were unable to derive a reliable value for -SH.

The assumption in equation (3) is that 20 residue hydrophobicities (ΔG_R) can be represented by five ASPs ($\Delta\sigma$s), provided that suitable values of $\Delta\sigma$ can be found. We now show that a consistent set of $\Delta\sigma$s can be derived from experimental data on free energies of transfer. The accessible areas A_i of residues in standard conformations can be calculated from known structures; we have adopted the areas calculated by Shrake and Rupley[21], which are close to those found by C. Chothia (personal communication); they are for the amino acid X in a Gly-X-Gly sequence in a typical extended conformation. The values of the $\Delta\sigma$s were determined by a linear least-squares fit of equations (3) to observed values for the free energy of transfer, ΔG_R, of the amino-acid side chains. The measured ΔGs were those determined by Fauchere and Pliska[25] from transfer free energies of amino-acid residue analogues from n-octanol to water. Our estimated ASP values (with their standard deviations) are:

$$\Delta\sigma(\mathrm{C}) = \ 16 \pm 2 \ \mathrm{cal\ \AA^{-2}\ mol^{-1}}$$

$$\Delta\sigma(\mathrm{N/O}) = \ -6 \pm 4$$

$$\Delta\sigma(\mathrm{O^-}) = -24 \pm 10$$

$$\Delta\sigma(\mathrm{N^+}) = -50 \pm 9$$

$$\Delta\sigma(\mathrm{S}) = \ 21 \pm 10$$

The quality of the fit is illustrated in Fig. 2, and the observed and calculated values are given in Table 1. The fit is generally good except for Lys and Cys. Note that the non-polar atoms C and S increase the free energy of the system as they are transferred from the interior of the protein to water. Polar atoms decrease the free energy in the same process; charged atoms cause a much larger decrease.

Solvation contribution

With $\Delta\sigma$ values, it is possible to estimate the solvation contribution to the free energy of protein folding, ΔG_s. This energy with respect to a reference state r is given by

$$\begin{aligned}\Delta G_s = {} & \Delta\sigma(\mathrm{C}) \sum_{\mathrm{C\ atoms\ i}} (A_i - A_i^r) \\ & + \Delta\sigma(\mathrm{N/O}) \sum_{\mathrm{N,\ O\ atoms\ i}} (A_i - A_i^r) \\ & + \Delta\sigma(\mathrm{O^-}) \sum_{\mathrm{O^-\ atoms\ i}} (A_i - A_i^r) \\ & + \Delta\sigma(\mathrm{N^+}) \sum_{\mathrm{N^+\ atoms\ i}} (A_i - A_i^r) \\ & + \Delta\sigma(\mathrm{S}) \sum_{\mathrm{S\ atoms\ i}} (A_i - A_i^r) \qquad (4)\end{aligned}$$

in which A is the solvent-accessible surface area of an atom in the folded state and A^r is that in the reference state[21]. In the usual way in which equation (4) is used, the reference state does not matter because the energies of the same polypeptide chain are compared in two conformations having a common reference state. This is true for the application described below.

Improperly folded structures

One potential use of equation (4) is to assess the stabilities of modified or redesigned proteins. To illustrate such a calculation, the models of Novotný *et al.*[1] for incorrectly folded proteins are useful. These models were generated by exchanging the 113 side chains on the correctly folded α-carbon backbone of haemerythrin[26] from *T. dyscritum* with those from the correctly folded, β-sheet backbone of an immunoglobulin variable light-chain (V_L) domain[27] having the same number of residues. Novotný *et al.* used an energy-minimizing computer program to make small annealing adjustments in coordinates, and to reduce the potential energies of the two incorrectly folded structures to local minima. These annealed structures then had satisfactory van der Waals contacts, with normal valence angles and bond lengths, but no explicit account had been taken of solvation effects. Novotný *et al.*[1] noted that there is greater exposure of apolar residues in the misfolded structures. To these model misfolded structures, as well as to their energy-annealed, correctly folded analogues, we have applied equation (4) to estimate the solvation contribution to the free energy of folding. Our procedure consists simply of: first, computing[22] solvent-accessible atomic areas of the four structures from atomic coordinates; and second, weighting each atomic area by its ASP, and summing.

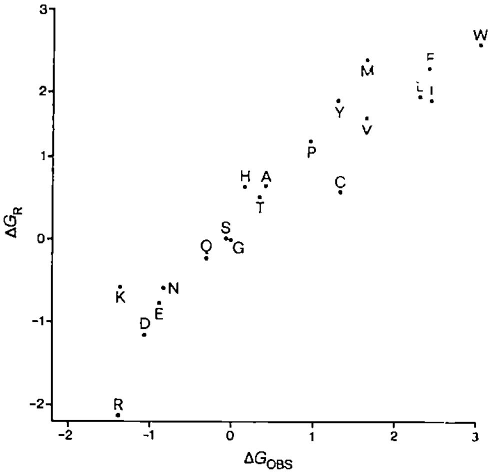

Fig. 2 Comparison of experimental values ΔG_{OBS} for free energies of transfer for amino-acid residues with the values of ΔG_R calculated from equation (3), using ASPs determined by linear least squares. The details of the least-squares fit are as follows. Fauchere and Pliska[25] deduced the hydrophobic parameter π for 19 amino-acid side chains as the difference between the logarithm of the measured distribution coefficients of the acetyl amino-acid amides and acetyl-glycine amide. Equation (3) was fitted to the free energies of transfer, $2.303\ RT\pi = \Delta G_{OBS}$, with the aid of NAG library routines G02BFF and G02CHF (Numerical Algorithms Group Ltd, Mayfield House, 256 Banbury Road, Oxford OX2 7DE, UK). In this fitting procedure, the difference between ΔG_R and ΔG_{OBS} is minimized by least-squares determination of the ASP values. The values of A for the appropriate atoms in each side chain are taken from ref. 21. For all residues, only the differences in area with the Gly residue are considered. Thus backbone atoms are ignored, except for the difference in exposed area for the α-carbon atom of glycine and of the other side chains. The deviation of points of the figure from a straight line can be explained by any of: (1) errors in measurements of ΔG_{OBS}; (2) inappropriate areas in equation (3); or (3) faulty assumptions in the formulation of equation (3) (see below). The multiple correlation coefficient R is 0.95, and the value of its square corrected for the number of parameters (ASPs), R^2_{COR}, is 0.88. The R^2_{COR} suggests that the separate ASPs for O^- and N^+ are justified, as is the sulphur ASP: with only a single type of charged atom, R^2_{COR} falls to 0.85 and R to 0.93; for only C/S and N/O ASPs, R^2_{COR} falls to 0.11 and R to 0.45. Fits to other hydrophobicity scales give different values for the ASPs. For example, the consensus scale of Eisenberg *et al.*[12], an average of five scales, yields $R = 0.97$ for a five-term fit. The ASP values for the consensus fit are similar to those reported here, but the O^- and N^+ ASPs have larger values. Despite the better fit to the consensus scale, the ASPs based on the data of Fauchere and Pliska[25] have been used in our calculations, in part because the absolute level of the consensus scale is unknown and in part because the new ASPs for the charged atoms seem more reasonable.

The solvation free energy is lower for the correct structures (Table 2). Both real structures have solvation free energies lower than the hypothetical, unfolded reference state by some 100 kcal $\mathrm{mol^{-1}}$, ~1 kcal per residue. Moreover, the solvation free energies for the real structures are markedly lower than for the incorrectly folded ones. Not only does each correctly folded structure have lower solvation free energy than the same polypeptide sequence folded improperly, but also each correct structure has lower free energy than the other sequence folded with the same backbone pattern. These results can be contrasted with the behaviour of traditional energy terms[1], which are not significantly different in the folded and misfolded structures.

When contributions to the solvation energy of folding for the natural structures are examined, interesting details emerge. For example, in the haemerythrin structure, 95 of the 113 side chains stabilize the solvation energy. Only one side chain, Asp 11, is destabilizing by so much as 1 kcal $\mathrm{mol^{-1}}$. For this side chain, both oxygen atoms are somewhat shielded from solvent relative to the extended reference structure. But for the protein as a whole, the process of folding from the extended reference state

Table 2 Solvation free energies of folding ΔG_s for an immunoglobulin V_L domain and haemerythrin

	V_L immunoglobulin domain	Haemerythrin
Correct fold	−106	−113
Incorrect fold (with the same sequence)	−72	−96
Net stabilization of correct structure	−34	−17

Values are calculated for the natural structures and the incorrectly folded structures (with exchanged amino-acid sequences) constructed by Novotný *et al.* Energies are given in kcal mol^{-1}. Equation (4) is used, with areas determined by the program ACCESS[22]. The uncertainty in the net stabilization of the correct structure was estimated from the standard deviations in the ASPs and by assuming that the fractional uncertainty in the sums of the atomic areas of each type is 0.05; this results in an overall uncertainty of ~10 kcal mol^{-1}.

yields −159 kcal for sequestering the 606 C and 3 S atoms away from the solvent (the sum of the first and last terms of equation (4)), while the partial covering of the 297 N/O, 17 O^-, and 21 N^+ atoms consumed only 25, 12 and 11 kcal mol^{-1}, respectively. Significant contributions to the stability of the folded state come from the apolar carbon atoms of the 29 Lys, Arg, Asp and Glu residues (a total of 41 kcal mol^{-1}). These contributions would be obscured or neglected in energetic models that are cast in terms of whole residue hydrophobicities; clearly, whole-residue hydrophobicities cannot account adequately for the folding energies of proteins.

Agreement with experimental data

Although it is reassuring that the estimated free energy of folding is lower for the real protein structures than for the incorrectly folded chains, this result falls well short of experimental verification of the method proposed here. Here we examine its assumptions and compare its predictions with experiment.

The principal assumption in the use of equation (3) to derive the ASPs is that the free energy of transfer is a linear function of the accessible areas of the constitutent atoms of the transferred molecule. This assumption is supported indirectly by the observed linearity of free energy with surface area for the transfer of many compounds from various non-aqueous liquids into water[15,28–31]. Of more direct bearing on the assumption is the accumulated evidence that molecular free energies of transfer can often be reckoned as a sum of energies for atomic groups[19]. This is not a new idea. Cohn and Edsall[17] made a critical analysis of evidence which suggested that the free energy of transfer of a chemical group such as $-CH_2-$, from ethanol and other apolar solvents to water is often independent of the molecule in which it is found. Some values for the free energy of transfer for various groups as compiled by Cohn and Edsall are given in Table 1, where they are compared with our new values calculated from equation (3). Generally, the computed values agree well in sign and magnitude with the experimental values, especially considering the diversity of the groups considered. The calculated values for side-chain transfers are also in reasonable agreement with the well-known measured values of Nozaki and Tanford[9] (Table 1). An exception to agreement in Table 1 is the free energy of transfer of the glycyl residue, for which equation (3) gives the wrong sign. This is probably because our model takes virtually no account of the partial charges on the amide N and O atoms. The reason is that the backbone atoms are omitted in the fitting procedure used to determine the ASPs, because the data being fitted are all differences between acetyl glycyl amide and the corresponding derivative of other amino acids. From the value in Table 2 for the free energy of transfer of the glycyl residue from ethanol to water, it is possible to estimate a crude value for the ASP for the amide N and O atoms at ~ −50 cal Å^{-2} mol^{-1}. If this value is qualitatively correct, then our solvation energies of folding are somewhat overestimated. To resolve this uncertainty, it will be necessary to fit a larger database of comparable free energies of transfer, which is not yet available.

An additional assumption in the use of equation (4) is that a non-polar liquid is an adequate model for the interior of a protein, as the ASPs derived from transfers between liquids are applied by equation (4) to transfer from liquid to protein interior. This assumption has been examined by Richards[24], who also considered amino-acid crystals as models for the protein interior. Richards concluded that an ASP somewhere in the range of 13–26 cal Å^{-2} mol^{-1} is appropriate for the transfer of apolar atoms. Our $\Delta\sigma(C)$ and $\Delta\sigma(S)$ values of 16 and 21 cal Å^{-2} mol^{-1} lie in this range, but may deserve revision as further free-energy data become available. The value for $\Delta\sigma(S)$, resting on only two measurements, is particularly subject to revision.

Atomic hydrophobic moments

In earlier work we described the amphiphilicity (asymmetry of hydrophobicity) of segments of regular protein secondary structure in terms of hydrophobic moments[32]. It was found that the hydrophobic dipole moments of neighbouring segments of secondary structure tend to oppose each other in correctly folded proteins[12], but not in incorrectly folded ones[33], and that hydrophobic moments can be used to classify helices on the basis of amino-acid sequences[34,35] and to detect periodicities[36,37]. These applications of hydrophobic moments were all formulated in terms of residue moments and can perhaps be made more precise with atomic-level moments.

The hydrophobic moment can be defined as an atomic property using the ASP values determined here. The hydrophobic dipole moment of a group of atoms is given by a sum over atoms i

$$\boldsymbol{\mu}_a = \sum_{\text{atoms i}} \Delta\sigma_i A_i \boldsymbol{r}_i - \langle \Delta\sigma A \rangle \sum_{\text{atoms i}} \boldsymbol{r}_i \qquad (5)$$

in which $\boldsymbol{r}_i$ is a vector from any origin to the position of atom i, and where the brackets indicate the mean value for all atoms of the group. The second term ensures that the value of $\boldsymbol{\mu}_a$ is independent of the choice of origin. When the sum in equation (5) is restricted to the atoms in a single side chain, a residue hydrophobic dipole moment is defined. This quantity is a measure of the amphiphilicity of the side chain, as distinct from its hydrophobicity. The values of these moments are tabulated in Table 1.

From these values it is apparent that the residues of greatest intrinsic amphiphilicity are Arg, Lys and Glu. In contrast, the most hydrophobic residues, Trp, Phe, Leu and Ile, all have small amphiphilicities. The direction of the hydrophobic moment is also defined by equation (5). This is expressed in Table 1 as the cosine of the angle between the direction of the moment and the direction of the vector from the α carbon to the side-chain centre. For the highly amphiphilic residues, the direction of the moment is nearly antiparallel to the α-carbon side-chain vector (cos θ near to −1). This is illustrated in Fig. 1*b* for Arg. Some of the most hydrophobic side chains (for example, Ile, Met and Phe) have moments nearly parallel to the α-carbon-centre vector (cos θ near to +1). Note that when the phenolic oxygen (with negative $\Delta\sigma$) is added to Phe to form Tyr, it reverses the direction of the moment (from +0.92 to −0.93).

Implications and extensions

How does the solvation free energy defined in equation (4) correspond to the component of the free energy of protein folding first described by Kauzmann as hydrophobic[3]? Kauzmann suggested that exposed apolar side chains increase the free energy of the system because they decrease the entropy of water. This effect on the free energy is described in equation (4) by the terms $\Delta\sigma(C)$ and $\Delta\sigma(S)$. Kauzmann's approach is extended in equation (4) by including the terms $\Delta\sigma(N/O)$,

$\Delta\sigma(O^-)$ and $\Delta\sigma(N^+)$. This has been done to introduce information from empirical free-energy measurements in a self-consistent way, and to impose a penalty in free energy for burial of charged and polar groups with a magnitude determined from experiments. These terms probably include contributions from electrostatic[38] and hydrogen-bonding effects as well. A full understanding of these contributions would require a knowledge of the structure of the molecules used to derive the ASPs, including states of protonation and hydration in both solvents. In short, ΔG_s includes contributions to the free energy of folding that go beyond the entropy change of the solvent. For this reason we call this energy the solvation free energy, rather than the hydrophobic free energy.

One use of equation (4) is in assessing the stability of proposed new proteins. These can either be genetically redesigned proteins or proteins designed for peptide synthesis. The energy of any model described in atomic coordinates can be tested against equation (4), although it may be necessary to supplement this equation with terms for other components of the folding energy. Another use is in energy-coupled X-ray phase refinement of protein structures[39-42]. In existing procedures, a model is determined that is the best compromise between the potential energy of the structure and the fit to the X-ray data. These methods do not go far enough in that it is the free energy, including solvation effects, that determines the structure. These effects could be incorporated by using ASPs as suggested here, along with the analytical method of Richmond[23], for computing accessible surface areas and their spatial derivatives. Similarly, the addition of a solvation energy term of the form of equation (4) could be made to molecular dynamics calculations. Finally, we note that the general method of computing solvation energy expressed in equation (4) could be developed further to compute the solvation contribution to the free energy for association of proteins with membranes or nucleic acids.

We thank Drs Novotný, Brucolleri and Karplus for making available the coordinates of the incorrectly and correctly folded protein structures described in ref. 1; Dr C. Chothia for his values of accessible surface areas of amino acids in extended polypeptide chains; Dr Richmond for use of his computer program ACCESS; and Drs D. Abrahams, F. R. Salemme and C. Schutt for discussions. D.E. acknowledges a Guggenheim fellowship and support from NIH and NSF. A computer program to calculate solvation energy according to equation (4) is available from the authors.

Inadequacy of Coulomb's friction law for particle assemblies

K. Kendall

ICI New Science Group, PO Box 11, The Heath, Runcorn,
Cheshire WA7 4QE, UK

Wherever powders are manipulated by mechanical means, adhesive and frictional forces act between the solid grains. For two centuries, these forces have been described by Coulomb's law[1], a law which originally proved useful in designing civil engineering structures, and which has since been profitably extended to the understanding of the powder flows in chemical plants[2]. However, we have now found that Coulomb's law is not adequate to explain the compaction of fine powders in the manufacture of ceramic articles, where it has been observed that friction appears to increase for smaller particles. This apparent increase in friction is explained by considering in detail the contact of loaded, adhesive, elastic spheres.

Consider the ideal experiment (Fig. 1*a*) in which a bed of particles is loaded onto and sheared along a polished plate of the same material[3]. The nominal shear stress F/A (where F is force and A is area) required to slide the powder across the plate under the normal stress W/A (where W is normal load) has usually been interpreted by Coulomb's law:

$$F/A = K + \mu W/A \tag{1}$$

where K represents the cohesive shear strength of the particle/plate assembly (that is, the shear stress experienced at zero normal load) and μ is the coefficient of friction between the surfaces[4]. This law, in combination with the geometrical constraints on powder motion first mentioned by Reynolds in 1885, has been much used to describe the deformation of powders and soils in complex stress states[5-7]. Here we demonstrate that equation (1) does not follow the experimental results satisfactorily, and we propose a new argument which provides an improved fit to the observed behaviour.

The problem of applying Coulomb's law to assemblies of fine particles is that the friction coefficient calculated from equation (1) does not generally match that measured in a standard friction test between macroscopic blocks of material. First, the calculated μ is often higher than expected: for example, sand particles of diameter 0.5 mm in water give $\mu = 0.45$ whereas two large quartz blocks give $\mu = 0.3$ (Fig. 1*b*). A second difficulty is that the friction coefficient increases as the grains are made smaller,

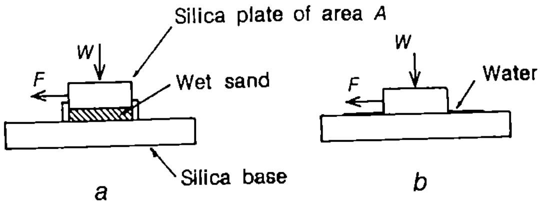

Fig. 1 *a*, Experimental set-up for measuring friction of wet sand particles pressed against a smooth silica plate. *b*, Friction measurement on macroscopic silica plates.

rising to $\mu = 0.6$ for wet sand of 0.01 mm diameter. Finally, the friction of powders does not remain constant as the normal pressure is increased, but falls substantially at high loads, in conflict with Coulomb's law. Therefore, a new theory is required to account for these curious effects.

The fundamental origin of Coulomb's law may be seen by considering a spherical particle in frictional contact with a smooth plane under normal load w and shear force f (Fig. 2). Because the particle experiences a surface attraction towards the plane as a result of van der Waals' force w_s, the total load on the contact is $w_s + w$ and the frictional force is thus

$$f = \mu(w_s + w) = k + \mu w \qquad (2)$$

which is the form of equation (1). Thus, Coulomb's law is the simplest expression for frictional resistance, taking into account both the external load and the interfacial attraction between the particle and the plane.

Equation (2) has been predominant in describing soil behaviour[8]; it has been re-derived by Derjaguin[9], and verified by Lazarev[10] for flat surfaces in extended molecular contact. It is used to this day to account for the friction of powders[11,12] and fibres[13] although it does not follow the results satisfactorily.

The difficulty with the simple Coulomb model is the assumption that the external load and the interfacial force are independent. This assumption is wrong, as indicated by recent studies on the contact of elastic spheres exhibiting surface attractions[14]. For a sphere of diameter D resting on a plane surface of the same material with interface energy Γ (the energy required to break unit area of contact) and normal load w, the effective load pressing the sphere onto the plane has been shown to be[14]

$$\frac{3\pi D\Gamma}{2} + w + \left[3\pi D w\Gamma + \left(\frac{3\pi D\Gamma}{2}\right)^2\right]^{1/2} \qquad (3)$$

so that the equation for shear force becomes

$$f = \frac{\mu 3\pi D\Gamma}{2} + \mu w + \mu\left[3\pi D w\Gamma + \left(\frac{3\pi D\Gamma}{2}\right)^2\right]^{1/2} \qquad (4)$$

This equation is similar to the Coulomb form of equation (2) in that the first term stems from surface attraction and the second term is due to the external load; it differs, however, from the Coulomb model in the extra term which gives the interdependence of the molecular forces and the applied load. It also differs from the recent theory for the sliding of adhesive spheres suggested by Savkoor and Briggs[15].

Equation (4) is useful in describing some of the anomalies reported previously. For example, it explains the nonlinearity of plots of friction force against normal load noted by Briscoe and Kremnitzer on polyethylene terephthalate fibres[13]. Figure 2 shows how the new theory follows the experimental data. The spread of friction results suggested a value of interface energy Γ of $\sim$0.01–0.04 J m^{-2}, in fair agreement with the value calculated from direct adhesion tests. Note that the apparent friction coefficient (the slope of the curve) is twice the true μ near zero load, but decreases to the correct value at high loads, or for large particles.

The predictions of equation (4) were tested experimentally, using the apparatus of Fig. 1*a* to determine the friction of wet silica powder. Sand was sieved into fractions and was loaded between smooth silica sheets, then sheared to measure the friction force. This friction force remained constant over many traversals of the silica, suggesting that the deformation was largely elastic, as assumed in the theory. Various loads were used, giving normal pressures close to 100 kPa, and the slope of the friction force/normal force curve was calculated. This slope was the apparent friction coefficient, μ_{app}, which was then compared with the theoretical value computed by differentiation of equation (4):

$$\mu_{app} = \frac{df}{dw} = \mu\left[1 + \left(1 + \frac{4PD}{3\pi\Gamma}\right)^{-1/2}\right] \qquad (5)$$

where $P \approx w/D^2$ is the normal applied pressure.

Figure 3 shows the experimental results for μ_{app} as a function of the particle size at a normal pressure of 100 kPa. The apparent friction coefficient achieved a maximum of 0.63 for the smallest grains, falling steadily for larger particles, and reaching a value of 0.34 for the macroscopic plates. The theoretical curve plotted from equation (5) gave a remarkably good fit to the data when the interface energy Γ was taken to be 2 J m^{-2} and the true friction coefficient was $\mu = 0.332$. Although this value of interface energy seems somewhat high for wet silica, a similar discrepancy has been noted in electron microscope studies of

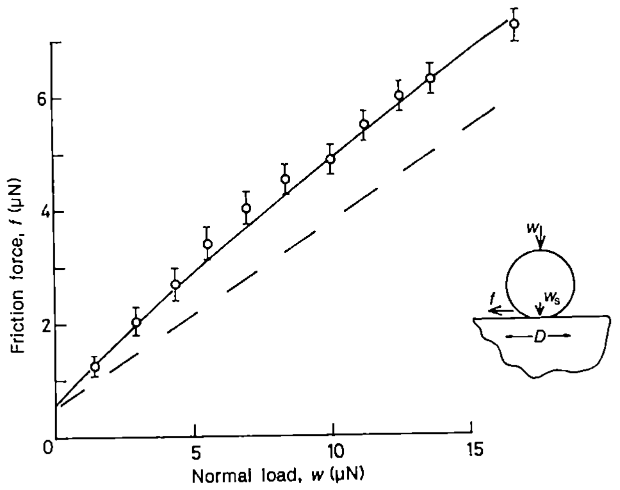

Fig. 2 Contact between a particle and a plate exhibiting interfacial attractive energy Γ under a normal load w and shear force f. The surface attraction between the spheres leads to a nonlinear relation between f and w [equation (4)] which differs from Coulomb's law at low loads but approaches Coulomb behaviour at high loads. ——, Curve derived from equation (4) with $\mu = 0.33$, $\Gamma = 0.01$ J m^{-2}; - - -, curve derived from Coulomb's law, $\mu = 0.33$; ○, results from ref. 13.

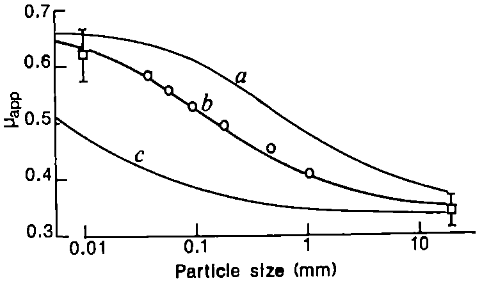

Fig. 3 Plot of μ_{app} against particle size derived from equation (5) for comparison with experimental results on wet sand. A good fit with the experimental results was obtained when the true friction coefficient was assumed to be 0.332 and the interface energy 2 J m^{-2}. *a–c*, Curves derived from equation (5) with $\Gamma = 10$, 2 and 0.1 J m^{-2}, respectively. □, Our results; ○, those of Rowe[3].

adhering metal particles, probably owing to the nonspherical nature of the grains[16].

It seems likely, therefore, that the new theory presented here offers the correct explanation for the failure of Coulomb's law in describing the odd frictional behaviour of fine powders, particularly those materials of high surface area which are used in the field of modern ceramics.

Secondary antiproton production in relativistic plasmas

C. D. Dermer & R. Ramaty

Laboratory for High Energy Astrophysics, NASA/Goddard Space Flight Center, Greenbelt, Maryland 20771, USA

Recent measurements[1-3] of the low-energy flux of antiprotons ($\bar{p}$) in cosmic rays give ratios of $\bar{p}/p$ which are greater by a factor of 3-5 than predicted by the simple 'leaky box' model of cosmic-ray propagation. Here we report on an investigation of the possibility that the low-energy $\bar{p}$ excess reflects an origin in p-p collisions in relativistic plasmas. Because of both target and projectile motion in such plasmas, the antiproton production threshold in the frame of the plasma is much lower than the threshold of antiproton production in cosmic ray interactions with ambient matter. The spectrum of the resultant antiprotons therefore extends to much lower energy than in the cosmic ray case. Sites at which matter is accreted by compact objects could be sources of the low energy antiprotons. Escape of the antiprotons could be mediated by antineutron production.

Golden *et al.*[1] have reported an antiproton to proton ($\bar{p}$/p) ratio of $5.2(\pm 1.5)\times 10^{-4}$ in the cosmic radiation in the energy range 4.7-11.6 GeV. Bogomolov *et al.*[2], on the basis of only two events, report a $\bar{p}$/p ratio of $6(\pm 4)\times 10^{-4}$ at energies between 2 and 5 GeV. Buffington *et al.*[3] report a $\bar{p}$/p ratio of $2.2(\pm 0.6)\times 10^{-4}$ between 130 and 320 MeV, and also determine that the antihelium to helium ratio $\bar{\alpha}/\alpha < 2.2\times 10^{-5}$ in the energy range 130-370 MeV per nucleon. Upper limits on previous antinucleus searches are also given here.

The simple 'leaky box' model of cosmic-ray propagation predicts a $\bar{p}$/p ratio smaller by a factor of 3-5 than the values measured in the Golden and Bogomolov experiments. Because of the kinematic cutoff associated with the high $\bar{p}$ production threshold in p-p collisions when one of the protons is at rest, the $\bar{p}$/p ratio predicted by this model is about two orders of magnitude lower than the value reported by Buffington *et al.*, even after the effects of solar modulation are taken into account[4]. The low $\bar{\alpha}/\alpha$ ratio, in comparison with the $\bar{p}$/p ratios, suggests a secondary origin of the $\bar{p}$, although primary cosmic-ray antiproton theories, with subsequent breakdown of the $A > 1$ antinuclei, have been proposed (see ref. 5).

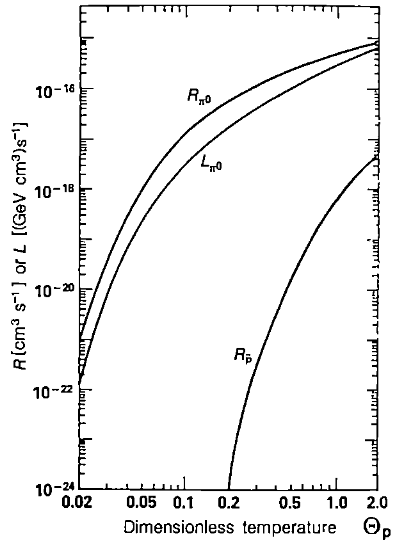

Fig. 1 The rate coefficients for secondary π^0 and $\bar{p}$ production from p-p collisions in a relativistic plasma at temperature $\Theta_p = kT/m_pc^2$. Also shown is the π^0 luminosity coefficient giving the total energy in secondary π^0 γ-rays produced at temperature Θ_p.

Theories of secondary $\bar{p}$ production in p-p collisions in the Galaxy are constrained by the observed galactic γ-ray luminosity. The observed antiproton flux $\phi_{\bar{p}}(E)$ implies a total galactic $\bar{p}$ production rate

$$Q(\bar{p}) \sim \frac{4\pi V}{c}\int_0^\infty dE \frac{\phi_{\bar{p}}(E)}{\beta\tau(E)} \sim (3.5\times 10^{-14} V/\tau)\bar{p}\,s^{-1}$$

where V is the galactic confinement volume and τ is the average galactic $\bar{p}$ residence time. Taking $V \sim \pi(15\,\text{kpc})^2\,(1\,\text{kpc}) \sim 1.2\times 10^{67}\,\text{cm}^3$ and $\tau \sim 10^7$ yr gives $Q(\bar{p}) \sim 2.1\times 10^{39}\bar{p}\,s^{-1}$. If the production of a secondary $\bar{p}$ is accompanied by the production of $\langle n \rangle$ π^0-decay γ-rays, the resultant γ-ray luminosity of the galaxy $Q(\gamma) \sim \langle n \rangle Q(\bar{p})$. In the case of the production of > 100 MeV photons in cosmic-ray interactions, $\langle n \rangle_{cr} \sim 2.7\times 10^3$, from the calculations of Stephens and Badhwar[6] and Tan and Ng[4]. If the $\bar{p}$ in the cosmic radiation are entirely cosmic-ray secondaries, the > 100 MeV luminosity of the Galaxy should, therefore, be at least $5.7\times 10^{42}\,\gamma\,s^{-1}$, in contrast to the value of $\sim 2.5\times 10^{42}\,\gamma\,s^{-1}$ deduced from the COS-B γ-ray observations[7]. This latter number is an upper limit, since it includes a significant contribution from bremsstrahlung and inverse Compton γ-rays.

Various models have been designed to either increase the $\bar{p}$ lifetime τ, incorporate additional $\bar{p}$ sources, or conceal the π^0 γ-rays. Although the integral production rate of $\bar{p}$ can then be made to agree with observations, most models still fail to predict a substantial low-energy $\bar{p}$ flux because of the low energy cutoff that results from secondary interactions with stationary targets, in disagreement with the observation[3]. Models that provide deceleration of the $\bar{p}$ after production or require that the Solar System occupies a special position in the Galaxy have also been proposed[8,9].

We examine the possibility that the low-energy antiprotons observed in the cosmic radiation are produced through secondary p-p interactions in relativistic plasmas in the vicinity of neutron stars or black holes. At proton temperatures $\theta_p = kT/m_pc^2 \gtrsim 0.2$ ($\theta_p = 1$ corresponds to $\sim 10^{13}$ K), a significant number of secondary $\bar{p}$ can be produced. We have calculated the rate coefficients and production spectra[10,11] for secondary $\bar{p}$ using the invariant cross-section of Tan and Ng[12] and the results are shown in Figs 1 and 2. We have also calculated the rate and luminosity coefficients from secondary π^0 production data. From Fig. 1 we find that the efficiency for $\bar{p}$ production compared with π^0 production is greater than in the cosmic-ray case for $\theta_p \gtrsim 0.5$, so the total π^0-decay γ-ray luminosity will not

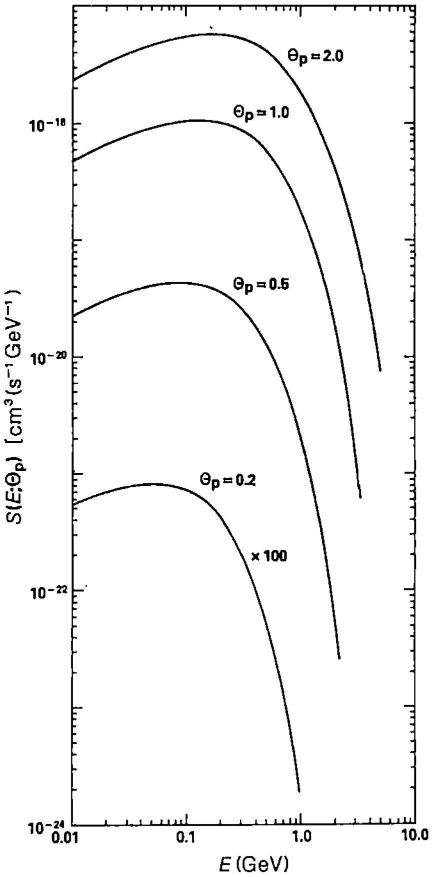

Fig. 2 Secondary $\bar{p}$ production spectra at various temperatures $\Theta_p = kT/m_pc^2$ are given as a function of kinetic energy E.

exceed limits implied by γ-ray observations of the Galaxy. In addition, several absorption processes likely to occur near compact objects, such as photon-photon or magnetic pair production, can further reduce the π^0 γ-ray luminosity.

The $\bar{p}$ spectra shown in Fig. 2 for a variety of temperatures extend to low energies without the appearance of the kinematic cutoff found in the cosmic-ray problem. The spectra peak at higher energies with increasing temperature, and exhibit an exponential decline above the peak temperature. But in all cases a very low-energy secondary $\bar{p}$ component is calculated, which could explain the low-energy $\bar{p}$ observation[3].

Possible production sites of the $\bar{p}$ include the galactic bulge binary X-ray sources or the objects associated with the γ-ray point sources (for example, CygX-3). Models for disk accretion[13] and spherical accretion incorporating shocks[14] could yield proton temperatures as high as $\Theta_p \sim 1$. Although the establishment of a thermal distribution of protons may not be possible at these temperatures, this assumption affords the simplest calculations. Preliminary estimates employing nonthermal proton spectra in relativistic plasmas suggest low-energy $\bar{p}$ spectra similar in form to the results of Fig. 2.

Transport of the secondary $\bar{p}$ from the production site can occur because antineutrons $\bar{n}$, produced in equal numbers as the $\bar{p}$ (ref. 15), are not confined by the ambient plasma magnetic field. The $\bar{n}$ will escape to the interstellar medium and subsequently decay into $\bar{p}$ (the calculations of Figs 1 and 2 refer only to these particles). Because of the finite lifetime of the $\bar{n}$, an upper limit can be placed on the mass of black holes that serve as production sites for the $\bar{p}$. Requiring that the marginally relativistic $\bar{n}$ escape to ~10 Schwarzschild radii implies a maximum black hole mass of $<10^7 M_0$. Past activity around such a massive black hole at the galactic centre could have produced the antiprotons without a large contemporaneous γ emission. A detailed comparison of $\bar{p}$ production in relativistic plasma with observations must also include distortions of the emergent $\bar{n}$ due to the intense gravitational field of the compact object, reacceleration and energy losses of the source spectrum in the galactic environment, and modulation in interplanetary space.

We have presented a model that can produce low-energy antiprotons through secondary p-p interactions in relativistic plasmas. Such a model is in agreement with the observation of low-energy antiprotons in the cosmic radiation and the observed γ-ray luminosity of the galaxy. Moreover, it agrees with the present lack of observations of antinuclei in the cosmic radiation, whose formation by secondary production processes is entirely negligible.

Specific role of transient O^-(s) at Mg(0001) surfaces in activation of ammonia by dioxygen and nitrous oxide

C. T. Au & M. W. Roberts

Department of Chemistry, University College, Cardiff CF1 1XL, UK

It has been established[1–3] that oxygen chemisorbed at a metal surface can activate an otherwise unreactive molecule, as in the activation of S—H, N—H, O—H and C—H bonds. We have now extended these studies to more complex systems involving co-adsorbed molecules in the hope of throwing some light on the mechanisms of heterogeneous catalysts. We have previously established the mechanisms by which unreactive molecular water, adsorbed on a Zn(0001) surface, is activated when co-adsorbed with nitric oxide[4], and have demonstrated N—H activation in ammonia co-adsorbed with nitric oxide at an atomically clean Mg(0001) surface at 295 K (Fig. 1*a* and ref. 5). Activation was attributed to surface oxygen generated in the dissociative chemisorption of nitric oxide. Here we establish the nature of the 'oxygen' species involved and reveal details of the molecular steps.

It is important to establish whether the 'oxygen' generated in the act of dissociative chemisorption of nitric oxide, that is, a short-lived species O^-(s), has any specific chemical reactivity that distinguishes it from the thermodynamically more stable surface 'oxide' species, O^{2-}(a), which was observed in the post-reaction XPS (X-ray photo-electron spectroscopy) study. Dynamic XPS over a wide temperature range is used to obtain information concerning the individual molecular steps.

We established first that a pre-oxidized Mg(0001) surface did not chemisorb ammonia at 295 K. Bulk MgO is also known to be unreactive to ammonia as judged by infrared spectroscopy[6,7]. The active oxygen species is clearly not the thermodynamically stable O^{2-}(a) species formed in the dissociative chemisorption of nitric oxide. However, dioxygen-ammonia mixtures also generate stable NH_2(a) species[8], which raises the issue of the possible steps that occur during the dissociative chemisorption of

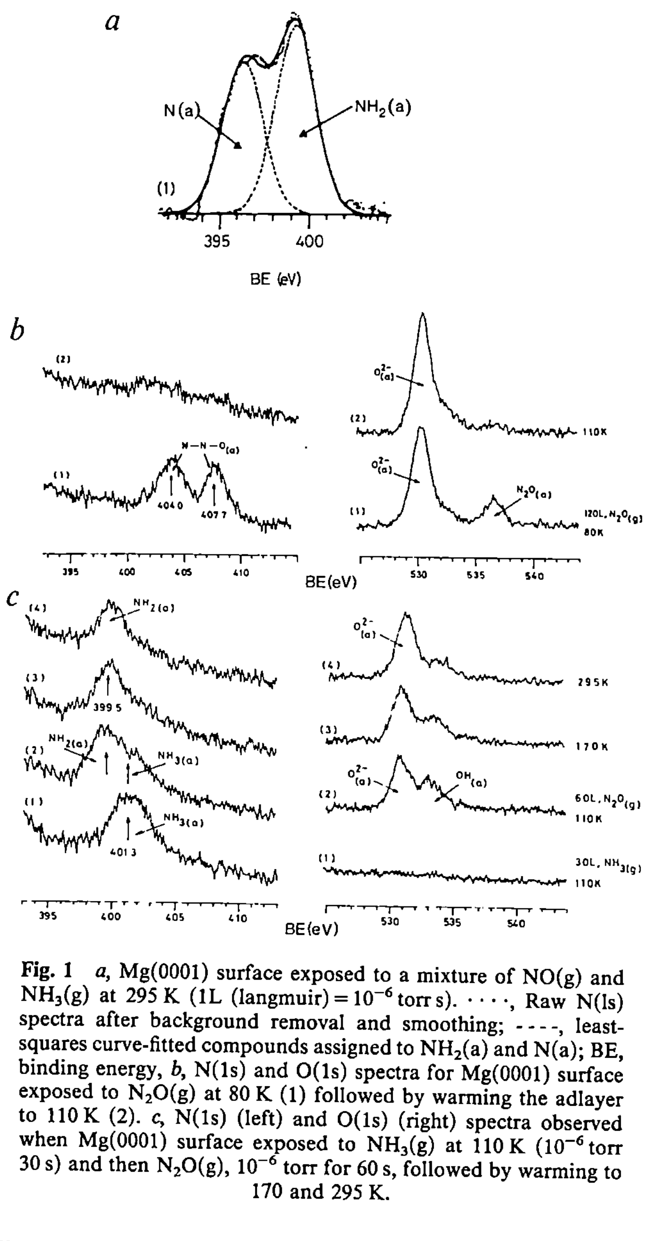

Fig. 1 *a*, Mg(0001) surface exposed to a mixture of NO(g) and $NH_3(g)$ at 295 K (1L (langmuir) = 10^{-6} torr s). · · · ·, Raw N(1s) spectra after background removal and smoothing; - - - -, least-squares curve-fitted compounds assigned to $NH_2(a)$ and N(a); BE, binding energy, *b*, N(1s) and O(1s) spectra for Mg(0001) surface exposed to $N_2O(g)$ at 80 K (1) followed by warming the adlayer to 110 K (2). *c*, N(1s) (left) and O(1s) (right) spectra observed when Mg(0001) surface exposed to $NH_3(g)$ at 110 K (10^{-6} torr 30 s) and then $N_2O(g)$, 10^{-6} torr for 60 s, followed by warming to 170 and 295 K.

dioxygen at a metal surface and leading to oxidation. As kinetic (XPS) data have established the existence of a molecularly adsorbed oxygen precursor in the oxidation of aluminium at low temperatures (77 K) and both XPS and ultraviolet photoelectron spectroscopy have established[4] the presence of $O^-(a)$ species during oxygen interaction with Zn(0001) surfaces, the following steps can be delineated for the dissociative chemisorption of oxygen at a metal surface

$$O_2(g) \rightarrow O_2(a) \rightarrow O^-(a) \rightarrow O^{2-}(a)$$

The step $O^-(a) \rightarrow O^{2-}(a)$ is initially kinetically fast at a Zn(0001) surface even at 77 K but with increasing $O^{2-}(a)$ concentration the process becomes activated so that at 77 K the $O^-(a)$ species represent a substantial (~60%) fraction of the $O^{2-}(a)$ concentration[4]. As the $O^-(a)$ species have been shown to abstract hydrogen from molecularly adsorbed water a mechanism of NH_3 activation could involve the intermediate $O^-(s)$. Note that there is no *a priori* reason why the above scheme for the dissociative chemisorption of dioxygen should not also include the $O_2^-(s)$ species and present at the surface as a transient. By studying the co-adsorption of ammonia with nitrous oxide starting at low temperature (110 K), this point can be resolved because N_2O is anticipated and shown to chemisorb (Fig. 1*b*) as indicated below. We use $O^-(s)$ to represent a surface transient and to

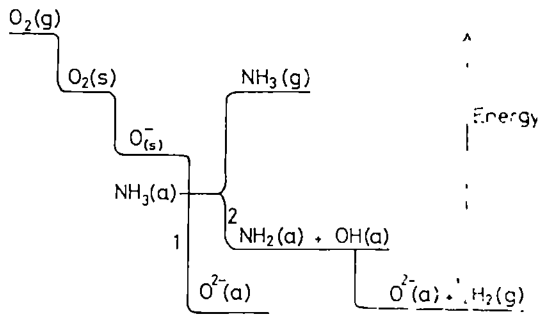

Fig. 2 Reaction scheme. Schematic representation of reaction pathways in the co-adsorption of 'oxygen' (N_2O, NO or O_2) and ammonia at 295 K; the ammonia diverts the 'oxygen' away from pathway 1(the oxide route) and along pathway 2 (the amide route) in spite of its very weak interaction with Mg(0001), ammonia desorbs at 170 K. Also an oxide overlayer, $O^{2-}(a)$, is, like bulk MgO, unreactive to ammonia under these conditions.

distinguish it from the more stable $O^-(a)$ and $O^{2-}(a)$ species for which direct XPS evidences is available,

$$N_2O(g) \rightarrow N_2O(a) \rightarrow N_2(g) + O^-(s) \rightarrow O^{2-}(a)$$

Figure 1*c* shows the N(1s) and O(1s) spectra observed when N_2O and NH_3 co-adsorbed at 110 K at a Mg(0001) surface was warmed to 295 K. Ammonia is physically adsorbed at 110 K and characterized by a single N(1s) peak at a binding energy of 401.3 eV. The calculated[2,9] surface concentration is 0.4×10^{15} cm^{-2}. When this adlayer is exposed to $N_2O(g)$, the N(1s) peak develops a second component at 399.5 eV. This is assigned[9] to the $NH_2(a)$ species. The O(1s) spectrum indicates surface oxide, $O^{2-}(a)$, and hydroxyl species with binding energies of 530.5 and 533.0 eV, respectively. On increasing the temperature first to 170 and then to 295 K, ammonia desorbs and intensity is lost from the 533.0-eV component to the 530.5-eV peak. The steps involved are as follows

$$NH_3(g) \xrightarrow{110K} NH_3(a)$$

$$N_2O(g) \xrightarrow{110K} N_2(g) + O^-(s)$$

$$O^-(s) \xrightarrow{110K} O^{2-}(a)$$

$$O^-(s) + NH_3(a) \xrightarrow{110K} OH(a) + NH_2(a)$$

$$OH(a) \xrightarrow{>110K} O^{2-}(a) + \tfrac{1}{2}H_2(g)$$

There is, therefore, good experimental evidence that the oxygen species participating in the activation of ammonia is a transient, $O^-(s)$, formed during the oxidation of Mg(0001) by dioxygen, nitrous oxide and nitric oxide. We emphasize that the surface amide species $NH_2(a)$ are strongly chemisorbed and could not have been anticipated on the basis of the lack of reactivity of NH_3 with both atomically clean Mg(0001) and with the 'bulk' MgO. Oxygen is, therefore, both a promoter and a poison for the activation; in its thermodynamically stable oxide state $O^{2-}(a)$, it is unreactive. We can envisage ammonia as an 'interceptor' molecule in that it influences the particular reaction pathway chosen by the co-adsorbed system. It is the efficiency of the NH_3—$O^-(s)$ step, that is, the ability of the ammonia to re-route the 'oxygen' along pathway 2 and away from pathway 1, that is crucial. This step can only be properly understood when knowledge of the surface lifetime of $O^-(s)$ becomes available. There may be alternative methods of generating the active oxygen species (such as lasers and discharges) so that unlikely reaction pathways, with (relatively) unfavourable thermodynamics can compete successfully with routes which at first sight, that is, with no knowledge of the details of the molecular events involved, would be considered most probable.

There are also important analogies to be drawn between our results and those reported recently[10,11] by Lunsford's group and commented on by Thomas[12] where activation of the C—H bond in methane by oxygen led to the formation of methyl radicals and surface hydroxyls. This was observed at high temperature (500 °C) with lithium-doped MgO where the active oxygen species was suggested to be O^-(s). The NH_2 species generated by hydrogen abstraction from ammonia at low temperature (Fig. 1) are also free radicals but, rather than desorb, are rapidly chemisorbed at the 'free' magnesium sites. Depending on the precise conditions at the surface, they may react with other species (if the number of Mg^0 sites is limited), including each other, and desorb as hydrazine. By changing the 'oxygen'-to-ammonia ratio, evidence for this alternative possibility has been obtained[8]. Note that in Lunsford's work the addition of water vapour to the oxidant was beneficial[10]. We have established elsewhere[9,13,15] that water vapour can enhance the presence of surface defects such as O^-(a) and OH(a) and which we have suggested[9] accounts for some oxides such as NiO · OH exhibiting specific oxidation behaviour to organic molecules.

A new method for measuring palaeomagnetic intensities

Mark Boyd

Department of Earth Sciences, University of Cambridge,
Madingley Road, Cambridge CB3 0EZ, UK

Because measurements of palaeomagnetic intensities (henceforth palaeointensities) are usually time-consuming and the success rate only poor, say, 30–50%, many palaeointensity values are based on as few as three experimental results. In an attempt to improve on this, a technique has been developed using automated equipment which is faster, and which can detect alteration of a sample during measurement, allowing the experiment to be terminated and another sample to be tried. The technique, described here, has been used on a collection of ancient bricks, and the results show the palaeofield at Cambridge (England) to have decreased from about 49 μT in AD 1511 to 42 μT in AD 1758, in good agreement with results using Shaw's method.

A SQUID (superconducting quantum interference device) magnetometer is used to measure the magnetic moment of a 4 mm diameter sample held at an elevated temperature within a compact non-magnetic oven that can be heated and cooled rapidly because of its low thermal capacity. Because the magnetometer is totally automated and the sample does not have to be repeatedly cooled to room temperature, as in the Thellier[1] and similar methods, palaeointensities can be obtained in 75 min; Shaw's method[2], by contrast, takes at least 140 min and the Thellier method can take anything from 3 h to several days.

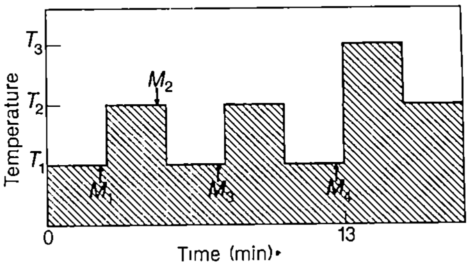

Fig. 1 Sequence of steps for one palaeointensity measurement typically a sample spends 130 s at equilibrium at each temperature.

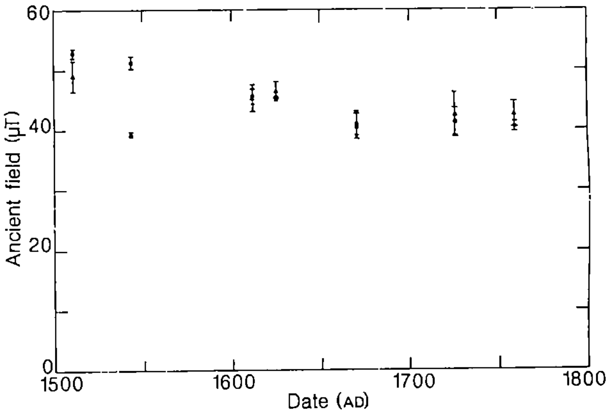

Fig. 2 Intensity of the geomagnetic field at Cambridge since AD 1500. ● Results from Shaw method; ▲, results from the present thermal method. Each point is the average result from three samples and the error bars one standard deviation. Only the AD 1543 bricks show significant disagreement.

The measurement sequence which allows the calculation of a palaeointensity (Fig. 1) begins by heating the sample to a base temperature T_1 and taking the first measurement of its magnetic moment M_1. Raising the temperature to T_2, a second measurement, M_2, is made before the sample is cooled back to the base temperature for the M_3 measurement, thermally demagnetizing the sample. At this point in the sequence, a magnetic field of known strength and direction is applied to the sample and maintained while the sample is again cycled to temperature T_2 and cooled to T_1, giving the sample a partial thermal remanent magnetization (PTRM). After removing the magnetic field the final measurement of the sequence M_4 is made.

This procedure effectively selects the magnetic grains which have blocking temperatures between T_1 and T_2. The natural remanent magnetization (NRM) preserved in this group of grains is the difference between M_1 and M_3 whereas the difference between M_4 and M_3 is the magnitude of the PTRM that these grains have acquired in the laboratory field. The ratio of these values combined with the laboratory field strength F_L gives the ancient field intensity, F_A

$$F_A = F_L \times \frac{M_1 - M_3}{M_4 - M_3}$$

To examine the grains with blocking temperatures between T_2 and T_3 the measurement cycle is repeated raising the base temperature to T_2. Because the M_2 measurement from the previous cycle is identical to M_1 for the present one, the initial measurement can be omitted from all subsequent cycles. Thus, six or seven cycles can be made before the Curie temperature of the sample is reached.

Although the sample quickly reaches thermal equilibrium after each heating and cooling phase, its magnetic moment is

Table 1 Two complete sets of experimental results

Temperature	M_1	M_3	M_4	M_2'	Ratio $\frac{M_1-M_3}{M_4-M_3}$	Alteration estimate $\frac{(M_2'-M_2)}{M_1-M_3}\times\frac{M_1}{M_2}$
No alteration						
110	11,546	10,918	11,669		0.84	-1.8
165	10,219	8,951	10,289	10,208	0.95	0.8
230	8,169	7,235	8,349	8,178	0.84	-1.2
310	6,348	5,202	6,434	6,337	0.93	1.3
375	4,356	3,252	4,554	4,369	0.85	3.0
440	2,502			2,528		
Alteration >7%						
110	3,922	3,658	4,013		0.74	6.6
165	3,459	3,308	3,671	3,476	0.42	20.4
230	3,137	3,054	3,337	3,166	0.29	0.4
310	2,829	2,672	3,039	2,830	0.43	30.9
375	2,413	2,195	2,612	2,457	0.52	−20.4
440	1,930			1,890		

The top set is from a sample which suffers no alteration. The ancient field intensities predicted at each temperature step are consistent. The lower set of results have values of >7% alteration effect, consequently this sample was rejected.

far from stable. Viscosity effects, the relaxation of grains with blocking temperatures higher than the sample temperature, mean that its magnetic moment is constantly changing. However, these viscous changes of moment can be allowed for and good results obtained provided. (1) each phase of the experiment, after the sample has reached a new thermal equilibrium, lasts the same length of time, typically 130 s; and (2) all measurements of the moment are taken at exactly the same length of time after thermal equilibrium is achieved. Usually the moment is averaged over the period 100-130 s.

Care must be taken that chemical or physical alteration of the magnetic carriers during measurement does not produce apparently acceptable, yet erroneous, results. This method provides several independent tests for such alteration. (1) The ratios obtained from each temperature step should be the same—this is equivalent to the linearity test used by the Thellier method. (2) Measurements of the samples' susceptibility are repeated at each base temperature which may show up any alteration. (3) The difference between M_2 and M_3 is caused by the increase in spontaneous magnetization of the oriented grains with blocking temperature above the temperature at which M_2 was taken. If an additional cooling step is included at the end of each cycle the saturation magnetization change can again be measured, checking for alteration that may occur during the heating phases between the two measurements. (4) A final heating step can be added to each cycle to repeat the M_2 measurement and monitor[3] any alteration that may occur during the cycle. This will not show any alteration that has occurred during heating immediately before M_2. However, it is unlikely that this alteration will have saturated; it will continue while the sample is held at this temperature. The repeat measurement M_2' should record the resultant change of moment which is expressed as a percentage of NRM lost in this single temperature cycle. Table 1 shows two sets of experimental data, the first sample did not suffer alteration but the second had to be discarded. An alteration effect of >7% is considered unacceptable.

Tests (3) and (4) show up alteration occurring only in the magnetic grains whose moment is actually contributing to the estimate of the ancient magnetic field. Alteration of the other magnetic grains is tolerable as they do not influence the ancient field estimate. Such alteration may be detected by conventional tests and cast unnecessary doubts on the results.

Four test samples were laboratory fired in a known field, using the above procedure in an attempt to recover the TRM field strength. The field strengths predicted ranged between +3.7 and −3.4% of the actual TRM field strength (Table 2).

Table 2 Results from four samples fired in a known magnetic field in the laboratory

Sample	TRM field (μT)	Field during experiment (μT)	Calculated cooling field (μT)	Age error (%)
1	67.56	61.93	67.32 ± 0.83	−0.4
2	33.78	39.41	32.63 ± 1.19	−3.4
2	33.78	33.78	33.68 ± 0.74	−0.3
3	36.60	33.78	35.60 ± 0.64	−2.7
4	59.38	53.73	61.60 ± 1.58	+3.7
4	50.86	48.03	52.35 ± 1.17	+2.9

The method has recovered these fields to within an average of 2%

To test this method, it was used on a collection of dated bricks taken from Colleges in the Cambridge area. These samples were also measured in the Cardiff laboratory[4] using the modified Shaw method[5]. Figure 2 shows that, except for one brick both sets of results were in good agreement. The average error between the two sets is 3.4%, four results being higher with the thermal method and two lower. These indicate that the geomagnetic field intensity at Cambridge has decreased smoothly from ~49 μT in AD 1511 to 42 μT in AD 1758. The original brick collection contained samples dated up to 1979, but all the bricks younger than 1758 exhibited unacceptable alteration and produced no results.

The major advantage of the thermal palaeointensity method described here is that its speed allows more samples to be measured so that the high failure rate, common to all thermal methods, becomes more tolerable. More results allow more accurate determinations of the ancient field. In addition, this experimental procedure automatically gives information on the spontaneous magnetization curve of the sample and a measurement of its d.c. susceptibility at each base temperature. This information in surplus to that required to produce an estimate of the ancient magnetic field but may give an indication of the magnetic carriers present in the sample.

This work was funded by N.E.R.C. grant GR3/4670 and the Northern Ireland Education Board.

McKenzie and Parker's early suggestion[1] that the Juan de Fuca plate is underthrusting North America has since been confirmed by numerous studies. Evidence for plate convergence along this junction includes: a sediment-filled trench[2–7], intense compressional deformation of the continental slope and shelf sediments[2–7], seafloor magnetic anomalies that extend beneath the continental slope[2,4], inland andesitic volcanoes[8], paired low/high heat flow and gravity anomalies[9,10], active onshore deformation[11,12], onshore crustal earthquakes with compressional axes parallel to the direction of plate convergence[13], sinistral strike-slip earthquakes along the Nootka Fault (Fig. 1)[14], and a well-defined Benioff–Wadati zone[6,15,16]. Here we report the results of a seismic reflection survey that has delineated two slabs of oceanic lithosphere underlying Vancouver Island, one that is currently being subducted and one that is underplated. These findings lead us to speculate that successive underplating of oceanic lithosphere may be an important process in the evolution and growth of continents.

A total of 205 km of deep seismic reflection data have been collected along the four profiles shown in the simplified geological map of southeastern Vancouver Island (Fig. 1). The VISP1 line crosses the width of the island and is almost coincident with one of the gravity profiles studied by Riddihough[10] and with the combined onshore/offshore seismic refraction line of Spence *et al.*[17]. Some three-dimensional control on the interpretation of VISP1 is available from the VISP3 line located 15–20 km to the east and from a short test line described by Clowes *et al.*[18]. The two southeasterly lines, VISP2 and VISP4, were designed to determine the attitudes and significance of the San Juan, Survey Mountain and Leech River faults.

Line drawings of the reflections are shown in Fig. 2 and a typical example of the data, with an accompanying simplified interpretation, is shown in Fig. 3. Two very prominent reflection zones, C and E in Figs 2 and 3, are observed on all seismic sections. They underlie most of southeastern Vancouver Island including the youngest allochthonous terrains along the southeastern tip of the island. Both reflection zones dip to the north-east, parallel to the direction of convergence between the Juan de Fuca and North American plates (Fig. 1).

Reflection zone E probably originates from the boundary region between the descending Juan de Fuca plate and the overriding North American plate. It lies at a depth of only ~23 km beneath the southern end of VISP1, based on migrated travel-times and velocities from Spence *et al.*'s[17] seismic refraction model, and is deepest at ~34 km beneath the north-central region of the island. Its overall dip in the vicinity of VISP1 is to the north-east at an angle of 9–13°. From Fig. 2, the average

Fig. 1 Simplified geological map of southeastern Vancouver Island showing the locations of the four seismic reflection profiles, VISP1 to VISP4, and the short seismic reflection profile, TEST, of Clowes *et al.*[18]. Geology is mostly from Muller[44], with minor modifications based on recent mapping programmes. The region to the north of the San Juan Fault is part of the exotic Wrangellia terrain of Palaeozoic and Mesozoic age. Between the San Juan and Leech River faults is an allochthonous mélange of Mesozoic metasediments and to the south of the Leech River Fault lies a volcanic terrain that may have been part of a Cenozoic seamount chain. The inset shows the location of the geological map with respect to the major plate boundaries.

depth to zone E is shown to be somewhat less than the depth to the active subduction zone of the seismic refraction model. However, Spence *et al.*[17] have demonstrated that the depth and structure of the subducting plate beneath Vancouver Island are only weakly constrained by the onshore/offshore seismic data. The location and attitude of zone E match well Riddihough's[10] estimates for the top of the subduction zone based on a variety of seismic and gravity data, and the northeasterly dip of 9-13° is in excellent accord with the $\sim$9° value obtained from an onshore/offshore seismic refraction study of the Washington continental margin[19] and the 11-15° dip of the Benioff-Wadati zone below southern Vancouver Island, Puget Sound and western Washington[6,15,16]. The shallow dip estimates are also consistent with the pattern of recent onshore deformation in this region[11] and with teleseismic waveforms recorded at seismographic stations on Vancouver Island and in western Oregon[20].

Towards the northern end of VISP1 there is some evidence for an increase in the dip of reflection zone E (Fig. 2). It is near to this location that the subducting plate in Riddihough's density models[10] begins to plunge more steeply into the mantle. Such a feature is common in other subduction zones[21] and is generally consistent with the steeply dipping slab of high-velocity material required to explain the pattern of travel-time anomalies to the north-east of Puget Sound[22]. The apparent absence of the deepest reflections beneath the northernmost region of VISP1 has at least two possible explanations. This part of the profile traverses the nose of a NW-SE-trending anticlinal ridge that exposes the oldest rocks on the island before crossing an escarpment onto a late Cretaceous sedimentary basin (Fig. 1), so the absence of deep reflections here may be related to geological and topographic complexities. Alternatively, if the dip of the subducting plate increases to a value in excess of $\sim$45°, as shown in some of Riddihough's density models[10] and as required by McKenzie and Julian's travel-time analysis[22], the relatively conventional data processing that we have applied would have effectively filtered out any reflections from this zone.

Figure 4 shows a contour map of two-way travel-times to the top of reflection zone E. Particularly noteworthy is the structure that is required to explain the variations in depth and attitude of the reflection zone between the western pair of seismic profiles (1 and 3) and the eastern pair (2 and 4). Of course, the dashed parts of the contour diagram are speculative; a major fault anywhere between the two pairs of profiles would allow an equally valid interpretation of existing data. Fig. 2 Line drawings showing the unmigrated reflections recorded on the four seismic reflection profiles. Vertical scale is two-way travel-time in seconds (T). All lines were recorded to 16 s with 30-fold coverage. Acquisition methods were similar to those used in the US by the COCORP group[45]. Final processing included single-fold trace editing, crooked line geometry and elevation corrections, automatic gain control, normal move-out corrections, trim statics using a correlation window of $T = 1$-12 s, common reflection point stacking, bandpass filtering of 8-40 Hz and trace-to-trace amplitude equalization using a $T = 4$-8 s window. Patterns at the top of each section show the surface geology crossed; an explanation of the various patterns is given in Fig. 1. On the VISP1 section the -1- border delineates the high-velocity (7.7 km s^{-1}), high-density (3.3 g ml^{-1}) block proposed by Spence *et al.*[17], and the -2- and -3- boundaries show, respectively, the Riddihough[10] and Spence *et al.*[17] estimates for the top of the actively subducting Juan de Fuca plate. C-C and E-E are prominent reflection zones that delineate the upper boundary of the high-velocity, high-density block (the underplated oceanic lithosphere) and the top of the actively subducting Juan de Fuca plate respectively. OF, Offshore (or Tofino[46]) Fault; BRF, Beaufort Range Fault; CRF, Cameron River Fault; CLF, Cowichan Lake Fault; LRF, Leech River Fault; SMF, Survey Mountain Fault; SJF, San Juan Fault (locations of faults are shown in Fig. 1). A typical example of the seismic reflection data is shown in Fig. 3.

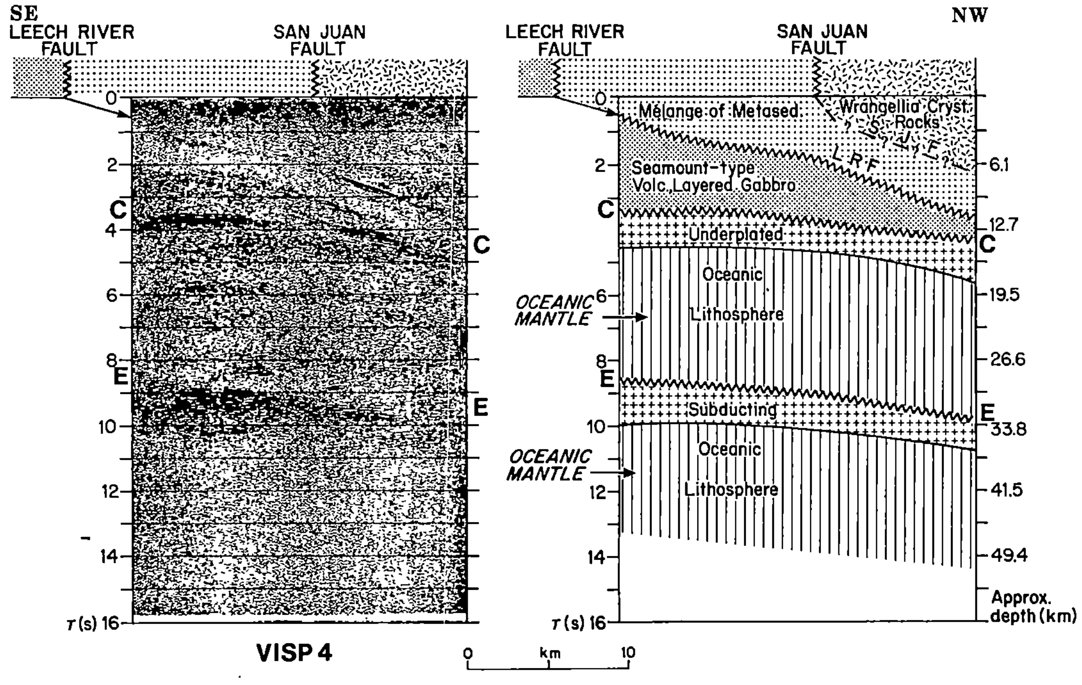

Fig. 3 A typical unmigrated seismic reflection section and simplified interpretation obtained from data recorded on Vancouver Island. Figure 1 shows the location of the profile and Fig. 2 (bottom right) shows a line diagram of the individual reflections recorded on the section. Patterns at the top of both the section and the interpretation diagram show the surface geology; an explanation of the various patterns is given in Fig. 1. The regions of + signs correspond to the reflection zones C and E. Approximate depths shown are based on the seismic refraction model of Spence *et al.*[17]. The seismic reflection data were recorded by Veritas Geophysical Ltd and processed by Veritas Seismic Ltd.

turing of the subducting plate in this general region have been predicted by Rogers[15] and by Keen and Hyndman[9] on the basis of seismicity patterns, fault plane solutions and the geometry of the Juan de Fuca–North American plate interactions. Some relatively deep strike-slip earthquakes in western Washington suggest that intra-plate faulting or segmentation may be a common feature of the downgoing Juan de Fuca plate[16].

The nature of the E reflection zone requires some discussion. On the migrated sections it is 3–5 km thick (1–1.5 s two-way travel-time) and has a strongly laminated character that could result from layered sediments, intercalated volcanics and sediments, layered igneous rocks or tectonic structures induced by underthrusting. Undeformed sediments are known to have been subducted to considerable depths beneath the forearc basins of several island arcs, including those of Japan[23,24], the Aleutians[25,26] and the Caribbean[27,28]. However, in the general region of Vancouver Island there are numerous single- and multi-fold seismic reflection profiles which show that the majority of sediments have been scraped off the descending oceanic plate to form the accretionary wedge that now constitutes the continental margin[2–7]. Reflection zone E is therefore unlikely to have originated from a simple stack of sedimentary layers riding on top of the descending oceanic plate. Nevertheless, it is feasible that the lowermost layers of lithified sediments have been taken down into the subduction zone and that these sediments and possibly the upper crystalline layers have been transferred or underplated to the base of the overriding plate. Successive underplating of this type would result in the formation of a thick layered sequence between the descending Juan de Fuca slab and the overriding North American plate. This particular process of accretion, termed subcretion by Karig and Kay[29], has been invoked by Von Heune[25] to explain some multi-fold seismic reflection data collected across the Aleutian trench and forearc basin.

Episodic and rapid sedimentation from the North American continent[2–7], combined with episodic volcanism involving extensive lava flows from the nearby oceanic spreading centres[30], have probably resulted in the widespread interlayering of oceanic basalts and sediments on the Juan de Fuca plate. Comprehensive studies across the northern parts of the Explorer plate (Fig. 1) and adjacent ridge segments have revealed ubiquitous interfingering of basaltic lavas and turbidites[3,30–33], and similar features are shown on the generalized geological cross-section of the central Oregon continental margin[34].

Based on the results of multi-fold seismic reflection surveys, high-quality seismic refraction surveys and deep-sea drilling, Talwani *et al.*[27] have proposed that interlayered extrusive and intrusive (mostly sills) rocks are the source of some laterally extensive reflections from within the acoustic basement of the small Caribbean plate. As similar lava flows and sills are expected to occur in the upper regions of the Juan de Fuca plate, some of the reflections in the E zone, particularly those near to the base of the zone, could have originated from structures within the descending oceanic crust.

Finally, at some subduction zones, notably those off the coasts of Java and Ecuador[24], there is a hint that layered reflections along the boundary of the descending plate only become pronounced landward of the trench. Layering of this nature could either be produced by the selective slicing away of sedimentary rocks from the underside of the accretionary wedge or it could result from brittle and/or ductile deformation induced by the relative motion between the two plates.

We interpret the region between reflection zones C and E as a tectonically underplated slab of older oceanic lithosphere, which was accreted to the base of Vancouver Island after the westward jump in the locus of subduction in Eocene times[35,36]. As shown in Fig. 2, our interpretation is supported by the gravity and seismic refraction models which require high-density (3.3 g ml^{-1}) and high-velocity (7.7 km s^{-1}) mantle-type material and velocity discontinuities at the appropriate shallow depths. The upper boundary of the high-velocity material at ~18 km depth is well-delineated from interpretations of the combined onshore/offshore seismic refraction line[17] and an intersecting refraction line that was recorded along the length of the island[37], so its coincidence with the base of reflection zone C is significant. On the seismic reflection lines the thickness of the interval between zones C and E varies from 9 to 18 km, which is comparable to the 17–20 km range that Spence *et al.*[17] derived for the thickness of the high-velocity mantle material in the descending Juan de Fuca plate.

Reflection zone C is strikingly similar to reflection zone E. It has a similar laminated character, an average thickness of 3–5 km and an overall dip to the north-east of 5–8°. It seems to have acted as a decollement zone to a number of major northeasterly-dipping structures, most of which can be projected to the surface where they coincide with mapped faults or plutonic contacts.

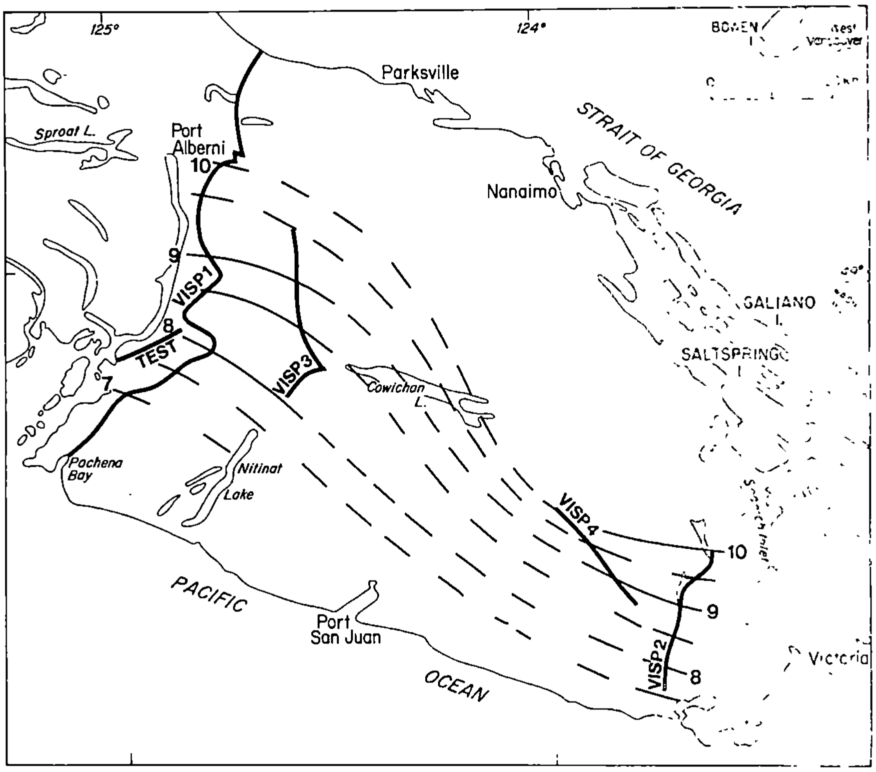

Fig. 4 Contours are two-way travel-times (unmigrated) (in s) to the top of reflection zone E. The curvature of the dashed contours between the western pair of seismic profiles (VISP1 and VISP3) and the eastern pair (VISP2 and VISP4) is speculative; a major fault anywhere between the two pairs of profiles would be an equally valid interpretation of the travel-time information.

Relative motion during the waning stages of this earlier phase of plate convergence would have occurred along these moderately dipping structures and along the decollement zone. A necessary consequence of our tectonic model is the removal of the lower lithosphere of the overriding plate during Eocene and earlier times.

It seems to us that under favourable but frequently occurring conditions, tectonic underplating of oceanic lithosphere at the base of convergent margins is a rapid means of adding large volumes of material to terrains that eventually become continental. This process is capable of creating root zones beneath the mountain ranges of active continental margins and of substantially increasing the crustal thicknesses of island arc-trench systems. In addition to our Vancouver Island example, thin slabs of underplated oceanic lithosphere have been proposed to underlie parts of Java[38], the Aleutians[25] and southern Alaska[39]. The underplated oceanic lithosphere would generally be of higher density, higher velocity and more basic than the overlying material. Across such terrains now interior to the continents, seismic refraction methods would resolve a broad-scale subhorizontal layering of the crust (including zones of high and low velocity), whereas seismic reflection techniques would see the pronounced reflection zones. Although many regions do not reveal such a simple image of the continental crust, a two- to four-layered crustal section with laminated reflections in the mid- to lower regions is a common feature on most continents[40]. Of course, we do not claim that underplating is the only or the dominant means of crustal thickening, but it is an important process that requires further investigation. In particular, the new mechanism could help to explain the anomalously high continental growth rates obtained for Precambrian shields[41,42]. Tectonic processes in Archaean times were probably dominated by the rapid movements of small, short-lived oceanic plates[41,43] and, like the present situation along the west coast of North America, subduction of the young and buoyant oceanic lithosphere would have occurred at relatively shallow angles.

We thank Drs J. Adams, M. Berry and R. Kurtz for critical reviews of the first draft of this manuscript and Dr E. Irving for pointing out the significance of Reymer and Schubert's work. This work was conducted as part of the LITHOPROBE program to study the three-dimensional structure of key geological targets on the Canadian landmass and adjacent offshore margins. We are grateful to Veritas Geophysical Ltd and Veritas Seismic Ltd for collecting and processing our data. This is LITHOPROBE paper 7; Earth Physics Branch contribution 1202.

Thermal expansion of silicate perovskite and stratification of the Earth's mantle

Elise Knittle*, Raymond Jeanloz* & Gordon L. Smith†

* Department of Geology and Geophysics, University of California, Berkeley, California 94720, USA
† Lawrence Livermore National Laboratory, Livermore, California 94550, USA

A pressure of 24 GPa and temperatures of about 2,000–3,000 K correspond to the observed 670-km seismic discontinuity which separates the upper and lower mantle. In such conditions the major minerals of the Earth's upper mantle, olivine ((Mg, Fe)$_2$SiO$_4$), pyroxene ((Mg, Fe)SiO$_3$) and garnet ((Mg, Fe, Ca)$_3$Al$_2$Si$_3$O$_{12}$) transform to a distorted (orthorhombic) perovskite-structured mineral ((Mg, Fe)SiO$_3$), or to a perovskite-dominated assemblage (refs 1–4). Because silicate perovskite is stable to at least 70 GPa, it is thought to be the most abundant mineral in the lower mantle and, possibly, in the entire Earth. Despite its importance, silicate perovskite was only discovered in 1976, and little is known about its physical properties because of the difficulty in achieving the conditions of pressure and temperature required for the synthesis of this phase. For example, the value of the thermal expansion coefficient of perovskite provides an important constraint on possible compositional models for the lower mantle[5–7]. We have recently produced sufficient amounts of (Mg$_{0.9}$, Fe$_{0.1}$)SiO$_3$ perovskite to measure its zero-pressure thermal expansion to 840 K by X-ray diffraction. At high temperatures, the average thermal expansion coefficient is 4×10^{-5} K^{-1}. Such a large value for the thermal expansion coefficient implies that standard models of upper mantle composition, such as pyrolite or garnet peridotite (Mg value ≈ 0.89), yield zero-pressure densities that are about 2% lower than that of the density of the lower mantle extrapolated to zero pressure conditions. This result suggests that the upper and lower mantle are chemically distinct, in accord with layered models of the thermal and convective state of the mantle.

We have measured the thermal expansion coefficient of (Mg$_{0.9}$, Fe$_{0.1}$)SiO$_3$ perovskite using a high-temperature Guinier X-ray diffraction camera, and diffraction patterns at room and higher temperature were collected on film. The perovskite was synthesized from a natural orthopyroxene ((Mg$_{0.88}$, Fe$_{0.12}$)SiO$_3$) above 35 GPa (350 kbar) and 2,000 K using laser heating through a Mao-Bell type diamond-anvil cell[8]. No pressure medium was used in the synthesis, and no ruby was used for pressure calibration, to prevent contamination of the perovskite. The sample pressure for the synthesis runs was determined from the force applied to the diamonds, which was independently calibrated as a function of pressure by the ruby fluorescence technique[9,10]. Lattice parameters of the quenched perovskite at ambient conditions were determined from the (002), (110), (111), (020), (112), (200), (210) and (211) diffraction lines, and gave lattice parameters of $a=478.3$ (±0.7) pm, $b=495.3$ (±0.8) pm, $c=688.6$ (±0.7) pm and a density $\rho=4.216$ (±0.004) Mg m^{-3}, in good agreement with previous results[11–13]. The high-temperature experiments were performed on quenched perovskite samples at zero pressure to temperatures exceeding 900 K (630 °C). Each high-temperature run required 35–50 diamond cell samples, which were loaded into a 200-μm fused-quartz capillary tube. NaCl was mixed with the perovskite to act as a temperature calibrant. At high temperatures, the lattice parameters and, therefore, the high-temperature volumes were determined from the (110), (020), (112), (200) and (211) diffraction lines. The perovskite, which is metastable at room temperature and pressure, reverted to enstatite between 840 and 875 K (567–602 °C) as evidenced from a rapid change in the X-ray diffraction pattern between these temperatures. Figure 1 shows the increase in volume (decrease in density) with temperature for perovskite at zero pressure. The b/a and c/a lattice-parameter ratios of the perovskite remained constant within the error bars to 840 K indicating no further distortion in the perovskite structure at high temperature. Similarly, Yagi *et al.*[14] found no conclusive evidence for a change in structural disrtortion with hydrostatic pressure to 8.4 GPa. From these two lines of evidence, we conclude that silicate perovskite does not undergo significant distortion from its zero-pressure orthorhombic structure at high pressure and temperature. Therefore, the physical properties of the quenched perovskite measured in the laboratory are relevant to silicate perovskite which exists at high pressure and temperature in the Earth's mantle.

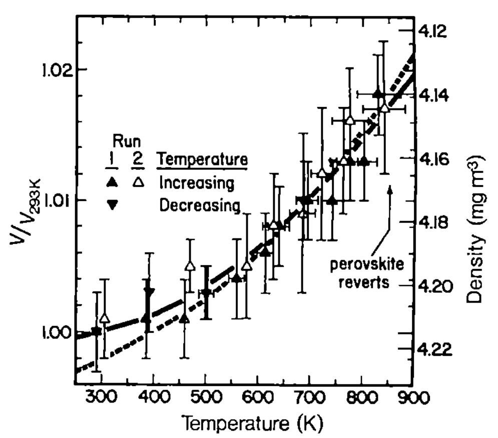

Fig. 1 The volume expansion of (Mg$_{0.9}$Fe$_{0.1}$)SiO$_3$ perovskite at zero pressure as measured by X-ray diffraction from room temperature to 840 K. Above 840 K the high-pressure perovskite structure reverts to the low-pressure structure of orthopyroxene. The curves through the data represent two fits to the measurements using the Suzuki formalism for Gruneisen's theory of thermal expansion. The solid line is the best fit to all of the data and is used to obtain the thermal expansion coefficient from 0 to 2,500 K. The dashed line is a fit to the high-temperature data only. Note that in the high-temperature region, between 450 and 850 K, the volume increases by 1.6%, which corresponds to an average thermal expansion coefficient of 4×10^{-5} K^{-1}.

Because the thermal expansion of perovskite cannot be measured above 840 K at zero pressure, our data must be extrapolated to temperatures for the Earth's mantle. We calculated the high-temperature thermal expansion coefficients using Gruneisen's theory of thermal expansion as formulated by Suzuki *et al.*[15,16]. In this procedure, we fit the measured data to obtain values for the Gruneisen parameter γ, the Debye temperature θ, the pressure derivative of the bulk modulus K_0' and the zero-temperature molar volume for perovskite (Table 1). Two acceptable fits to the data were obtained as indicated in Fig. 1.

Comparison of the high-temperature, zero-pressure perovskite densities can be made with the density and temperature of the decompressed lower mantle. Based on seismic observations, the bulk of the lower mantle appears to be homogeneous and adiabatic[17–19], and an Eulerian finite strain formalism can be used to extrapolate the density of the lower mantle adiabatically to zero-pressure, high-temperature conditions as was first done by Birch[19–22]. These calculations give a decompressed value of 4.00±0.01 Mg m^{-3} for the zero-pressure, high-temperature density of the high-pressure mineral assemblage comprising the lower mantle.

The temperature of the lower mantle on adiabatic decompression is uncertain. However, an estimated lower bound for this temperature, 1,700 (±250) K (~1,400 °C), is based on the phase equilibria of the olivine-spinel phase transitions which are thought to occur at 400 km depth[20,23–25]. If the mantle is stratified and the 670-km discontinuity is a thermal as well as a chemical boundary layer, the zero-pressure temperature of the lower mantle adiabat may exceed 2,000 K (ref. 25).

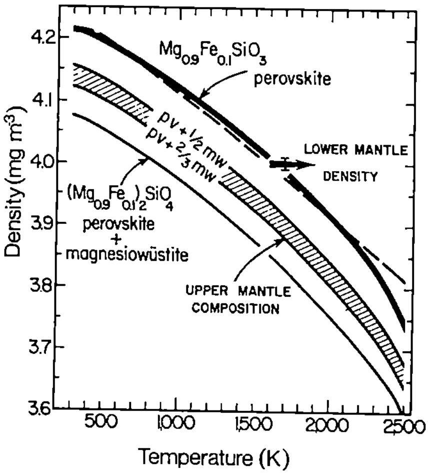

Fig. 2 Densities of proposed lower mantle assemblages (curves) are compared with the adiabatically decompressed values of density and temperature for the lower mantle (bold arrow). The zero-pressure value of the lower mantle density is well constrained (4.00±0.01 Mg m^{-3}), but only a minimum value for the lower mantle adiabat (zero-pressure temperature of 1,700 K) is known with confidence: the bold arrow illustrates that higher temperatures are possible. The zero-pressure density of (Mg, Fe)SiO$_3$ perovskite was extrapolated to high temperatures using the thermal expansion coefficient measured in this study (the solid and dashed bold curves correspond to the best fit and the high-temperature fit, respectively, shown in Fig. 1). A mineralogical model that satisfies the observed lower-mantle density consists of (Mg, Fe)SiO$_3$ pyroxene alone, in its high pressure perovskite phase. Lower-mantle assemblages consistent with a uniform mantle composition are indicated by the shaded band labelled 'upper mantle composition' (bounded by compositions between 1:1 and 2:1 olivine:pyroxene ratios, with pv and mw referring to perovskite and magnesiowüstite phases). All the models are based on $X_{Mg}=0.89$ (refs 27, 28) and the measured pv-mw partition coefficients[29,30]. None of the proposed upper mantle compositions or olivine alone (1:1 pv:mw) satisfy the observed lower mantle density at the appropriate conditions.

Table 1 Thermal expansion parameters for (Mg, Fe)SiO$_3$ perovskite

	γ	Θ(K)	K_0'	Molar volume at 0 K (V(0 K), cm^3 mol^{-1})
Best fit	1.77	525	7	24.46
High-temperature fit	2.20	825	4	24.39

Equation for volume at temperature T (see refs 15, 16):

$$V(T)=\frac{V(0\,\text{K})}{2k}\left[1+2k-((1-4kE)/Q)^{1/2}\right]$$

where $k=(K_0-1)/2$; $E(T,\Theta)=45\,RT(T/\Theta)^3\int_0^{\Theta/T} z^3/(e^z-1)\,dz$, $Q=K_0V(0\,\text{K})/\gamma$; $K_0=260(\pm 20)$ GPa (ref. 14).

Figure 2 shows the effect of temperature on the densities of perovskite (pv) and several perovskite-magnesiowüstite (pv-mw) assemblages compared at zero pressure with the density and temperature inferred for the lower mantle. The thermal expansion of perovskite is extrapolated to high temperatures using the data summarized in Table 1, whereas that of magnesiowüstite has been measured to 1,300 K (the mean thermal expansion coefficient from 300 to 1,300 K is 4.8×10^{-5} K^{-1})[15,26]. The region labelled upper mantle composition on Fig. 2 is bounded by the high-pressure phases which would result from a composition of olivine:pyroxene ratio between 1:1 and 2:1 (refs 27, 28). In each case, the upper mantle minerals are assumed to contain a ratio of magnesium to iron plus magnesium endmember components (X_{Mg}) of 0.89. The partitioning of iron between the resulting high-pressure phases was calculated using the partition coefficients determined by Bell *et al.*[29] and Ito and Yamada[30]. Also included in Fig. 2 is the change in density with temperature for an olivine-only composition (1 pv: 1 mw). It can be seen that the olivine-rich representative upper mantle compositions do not coincide with current estimates of the zero-pressure density and minimum adiabat temperature of the lower mantle (bold arrow).

To match the observed density of the lower mantle, a small but apparently significant enrichment of iron or silica (or both) is required relative to the composition of the upper mantle. If only iron enrichment is considered (upper mantle olivine:pyroxene ratio of 1:1 to 2:1) a value $X_{Mg}\leq 0.84$ (±0.02) is required to match the zero-pressure density of the lower mantle (4.00 (±0.01) Mg m^{-3} at 1,700 K). In contrast, current estimates of the average upper mantle composition yield $X_{Mg}=0.89$ (±0.02) (refs 6, 7, 27, 28). Our results are unlikely to be sensitive to the presence of minor components such as aluminium or calcium[7,20]. Nevertheless, we cannot uniquely determine the composition that is required to satisfy the observed properties of the lower mantle because of the tradeoff between the effects of iron content, silica content and temperature. For example, a pure perovskite composition with $X_{Mg}=0.87$ (±0.01) coincides with the lower mantle density at 2,000 K, an adiabat temperature consistent with the presence of a thermal boundary layer associated with a compositional change at 670-km depth[35].

The idea that the upper and lower mantle are chemically distinct has been previously suggested from geophysical, petrological and geochemical arguments[31-34]. Based on our new data on the high-temperature properties of perovskite we also find that the conventional model of upper mantle composition (such as peridotite with $X_{Mg}=0.89$ or pyrolite[27,28] seems not to be consistent with the observed lower mantle density. We cannot distinguish between possible iron enrichment or silica enrichment of the lower mantle, but are led to conclude that the 670-km discontinuity represents a change in average chemical composition of the Earth's mantle. Compositional stratification at this depth, in turn, suggests that the convection pattern within the mantle is predominantly two-layered, and that the timescale for the thermal evolution of the Earth's interior is considerably longer than the 1,000–2,000 Myr expected with unlayered, whole-mantle convection[35]. The presence of chemical stratification in the mantle depends on a delicate balance between the compositionally-induced density change and the Raleigh number for lower mantle convection, because at sufficiently large Raleigh number, convection would destroy any chemical layering (see refs 36–38). Although some leakage may occur between the upper and lower mantle[19,39], our data suggest that the intrinsically higher density of the lower (relative to the upper) mantle impedes mantle-wide mixing and results in a chemical and thermal boundary layer at 670-km depth.

^{187}Os/^{186}Os in marine manganese nodules and the constraints on the crustal geochemistries of rhenium and osmium

Martin R. Palmer* & Karl K. Turekian

Department of Geology and Geophysics, Yale University, Box 6666,
New Haven, Connecticut 06511, USA

During their formation, marine manganese (or more properly ferromanganese oxide) nodules include and commonly concentrate elements dissolved in seawater. This attribute makes them especially valuable recorders of the isotopic composition of elements supplied to the oceans having radiogenic isotopes, for these can be used in exploring crustal composition and evolution[1-5]. From measurements of ^{187}Os/^{186}Os ratios in marine manganese nodules and comparison with the ^{143}Nd/^{144}Nd ratios of the same nodules, we have calculated the Os isotopic composition and the osmium and rhenium concentrations of the weatherable portion of the continental crust, together with the proportions of 'ultramafic' and 'granitic' rock that constitute this crustal mass.

Our earlier studies in this laboratory[5,6] sought to relate the Os isotopic composition of marine manganese nodules to the sources of Os in the oceans. ^{187}Re decays ($\lambda = 1.52 \times 10^{-11}$ yr^{-1}) to form ^{187}Os. Variations in the ^{187}Os content of Os are commonly reported as the ^{187}Os/^{186}Os ratio since ^{186}Os is not radiogenic and is approximately equal in abundance to ^{187}Os in primitive materials such as meteorites[7]. The ^{187}Os/^{186}Os ratio depends on the age of the system and its ^{187}Re/^{186}Os ratio. The ^{187}Os/^{186}Os in manganese nodules records the mixing in the oceans of Os from systems with different ages and ^{187}Re/^{186}Os.

To unravel these sources and their properties, additional information is required. ^{87}Sr/^{86}Sr is a possible aid, but it depends mainly on temporal changes rather than regional diversity to recover such information[5]. Lead isotopes are complex and show perhaps too high a sensitivity to their sources[1] for our purposes. Variations in the ^{143}Nd/^{144}Nd ratio in manganese nodules have been well established and appear to provide the necessary constraint to the understanding of the ^{187}Os/^{186}Os texture of the oceans. Turekian and Luck[6] made an initial attempt at coupling the ^{187}Os/^{186}Os and ^{143}Nd/^{144}Nd systems to decipher sources of Os to the oceans. We now report additional Os isotopic data on nodules previously analysed for Nd isotopes and refine the interpretations made earlier.

The experimental procedures for measuring Os isotope ratios in manganese nodules have been discussed elsewhere[5,8]. Briefly, the technique consists of dissolving 10 g of the sample in a warm oxalic acid solution followed by distillation to extract the volatile OsO_4. This is then converted to $OsCl_6^{2-}$, purified on an ion-exchange column and plated on a silicon chip. The chloride salt is converted to the metal in a vacuum furnace. The actual Os isotopic composition is determined by secondary-ion microprobe mass spectrometry using the MIT-Brown-Harvard consortium Cameca IMS-3f ion microprobe. Osmium concentrations were determined in a few samples by isotope dilution.

The ^{187}Os/^{186}Os ratios measured in this study are listed in Table 1, together with those determined by Luck and Turekian[5]. All errors are 2σ of the mean. The data set is too small to provide an unambiguous judgement about details of the regional differences in ^{187}Os/^{186}Os, but the following observations can be made: (1) the mean values of the Atlantic, Pacific and Indian oceans are indistinguishable; (2) the largest range in ^{187}Os/^{186}Os of these basins occurs in the Atlantic (5.2-10.9); (3) some areas of an ocean basin have relatively homogeneous values, whereas others (such as, the eastern North Atlantic) show large differences within relatively small distances (see Fig. 1).

Turekian and Luck[6] have demonstrated that the Os extracted from manganese nodules, using the techniques discussed above, is virtually free of ^{187}Os produced *in situ* from the decay of ^{187}Re or Os associated with meteoritic debris trapped in the nodule. Although they addressed the problem of the contribution of magnetic spherules of meteoritic origin included in nodules, they assumed that all meteoritic debris is deposited on the ocean floor as particles. However, if all the meteoritic debris did go into solution, the meteoritic flux of osmium to seawater could be three times the riverine flux[9]. This would virtually homogenize the ^{187}Os/^{186}Os of the oceans. Clearly, this is not the case. Brownlee *et al.*[10] have recently demonstrated that Os and Ir occur as metallic 'nuggets' of ~10-μm diameter within magnetic spherules produced by the oxidation of meteoritic iron grains, probably during passage through the atmosphere. Therefore, because Os and Ir remain as refractory metals, they are less likely to be dissolved than some other elements of meteoritic origin. Hence, the measured ^{187}Os/^{186}Os ratios are the result of the integration of sources of dissolved Os with different isotopic compositions supplied to the oceans, primarily from terrestrial sources, and deposited in the nodule.

The strong differences in ^{187}Os/^{186}Os within ocean basins, and in some cases between nodules in close proximity, indicate that Os has a short mean oceanic residence time (~10^2 yr). For this reason, the relative input rates of Os of different isotopic compositions to each basin will be imprinted in the manganese nodules forming there.

We now characterize the potential sources of Os to the major ocean basins by coupling measurements of ^{143}Nd/^{144}Nd and ^{187}Os/^{186}Os in manganese nodules. The result of these calculations yields the ^{187}Os/^{186}Os ratio of the continental crust. This will provide constraints on the average Re/Os ratio of the crust and point to directions for verification. It will also provide information concerning the sources of mantle-derived Os to the different ocean basins. We draw on a model previously described[6] but with some modifications. Whereas before regional ^{143}Nd/^{144}Nd values were used, in the present study both Os and Nd isotopic measurements are available for each nodule.

We treat each of the major oceans separately, starting with the Pacific because of its size, relatively simple water structure compared with the Atlantic and the greater homogeneity of the ^{187}Os/^{186}Os ratios there.

To determine the ^{187}Os/^{186}Os ratio of the continental crust

---

* From refs 2–4.

that is recorded by the Pacific nodules, we make the following assumptions, most of which are reasonable in the face of our current ignorance: (1) the present-day $^{187}Os/^{186}Os$ ratio of mantle-derived material is 1 (ref. 7); (2) the dominant source of mantle-derived Nd and Os in the Pacific is the alteration (low temperature and hydrothermal) of ocean island basalt (OIB) represented by Hawaii and other 'hotspot' islands and seamounts; (3) the supply of Os and Nd from tholeiitic mid-ocean ridge hydrothermal vent systems is negligible[11]; (4) Nd and Os are released congruently during weathering and alteration; (5) the continental $^{143}Nd/^{144}Nd$ ratio supplied to the Pacific Ocean is the average of values for the major rivers flowing into the Pacific Ocean basin[12]; (6) the mean oceanic residence times of Os and Nd are short relative to the mixing times of the oceans (see above); (7) Nd and Os in labile sites in deep sea deposits define the isotopic composition of provinces within the ocean basins; (8) in the absence of a significant amount of reliable crustal Os concentration data, we assume the Os/Ir ratio is approximately 1, as determined in meteorites and ultramafic rocks[13-15]. This ratio refers to the component of Os having a mantle isotopic imprint.

The continental crustal $^{187}Os/^{186}Os$ ratio can then be obtained from[6]:

$$R_c = \frac{\dfrac{[Os]_c}{[Nd]_c}\cdot\dfrac{\varepsilon_b-\varepsilon_s}{\varepsilon_s-\varepsilon_c}R_s+\dfrac{[Os]_b}{[Nd]_b}(R_s-R_b)}{\dfrac{[Os]_c}{[Nd]_c}\times\dfrac{\varepsilon_b-\varepsilon_s}{\varepsilon_s-\varepsilon_c}}$$

where R_c is the $^{187}Os/^{186}Os$ ratio of the continental crust; R_s is the $^{187}Os/^{186}Os$ ratio of the sample; $R_b = 1$, $^{187}Os/^{186}Os$ ratio of the 'mantle' source (OIB); $\varepsilon_c = -10.7$, ε_{Nd} (O) of the continental crust supplying the Pacific Ocean; ε_s is the ε_{Nd} (O) of the sample; $\varepsilon_b = +6$, ε_{Nd} (O) of the 'mantle' source (OIB); $[Nd]_c = 32.6$, Nd concentration (p.p.m., parts per 10^6) of the crust; $[Nd]_b = 35$, Nd concentration (p.p.m.) of the 'mantle' source (OIB); $[Os]_c = 0.081$, the Os concentration (p.p.b., parts per 10^9) of the crust; $[Os]_b = 0.44$, the Os concentration (p.p.b.) of the 'mantle' source (OIB).

The sources of the data are listed in Table 2. Note that the absolute concentrations of Os and Nd are not required, but rather their ratios in the major rock types are used in the calulations. In crustal rocks, the Ir/Nd ratio is fairly constant (see Table 2). A sensitivity test conducted for reasonable variations in the parameters used in the equation above demonstrated that the calculated continental crustal $^{187}Os/^{186}Os$ ratio does not vary enough to alter significantly the conclusions presented below. (Hydrothermal ferromanganese deposits are not considered here.)

This calculation has been performed for all the Pacific nodules and the results are summarized in Table 3. The average $^{187}Os/^{186}Os$ ratio for the continental crust is 30. Thus ~25% of the Os found in Pacific manganese nodules is from continental crustal sources and the remaining 75% is from OIB alteration.

If we assume that the average age of the continental crust being drained by the major rivers flowing into the Pacific is equal to that of the continental crust being drained by Atlantic rivers[12], ~25% of the Os in the Atlantic manganese nodules is also derived from the continental crust, because the mean $^{187}Os/^{186}Os$ of both oceans is approximately the same. (Actually the average $^{143}Nd/^{144}Nd$ of the Atlantic feeding rivers is slightly lower than those for the Pacific[12], but the differences are too small to be of significance.) Atlantic manganese nodules, however, unlike those from the Pacific, have $\varepsilon_{Nd}(O)$ values that fall within the range for the average continental crustal value of -11.4 ± 4.0 (ref. 12). The source of the mantle-derived Os cannot, therefore, be the alteration of high Nd rocks such as OIB that are so abundant in the Pacific. We believe that these high Os, low Nd sources in the Atlantic are ultramafic rocks. Specifically, we identify them as the commonly serpentinized ultramafic rocks associated with the fracture zones along the mid-Atlantic ridge.

The Os concentration of peridotites is approximately two orders of magnitude higher than that of the continental crust and one order higher than OIB. Because ocean floor peridotites are virtually all strongly altered to serpentinite[16], the Os in peridotites is probably available for release to the oceans at the time of alteration. These aspects of the process have still to be investigated. Ocean floor peridotites are generally restricted to the walls of fracture zones associated, with the relatively slow spreading mid-Atlantic and the Atlantic–Indian ridges[16-19] (see Fig. 2). Very few peridotites have been recovered from the Pacific fracture zones. The low concentration of Nd in peridotites[20], relative to other mantle oceanic rocks indicates that they are not a significant source of Nd during submarine weathering or hydrothermal alteration.

From the continental crustal $^{187}Os/^{186}Os$ ratio of 30 we can determine the average Re/Os ratio by assuming a mean continental crust age of 2×10^9 yr (ref. 12, for example) and the establishment of the crust 4×10^9 yr ago. Assuming a constant rate of continental growth and equal availability to weathering of all age rocks, a $^{187}Os/^{186}Os$ ratio would correspond to a $^{187}Re/^{186}Os$ of ~1000, that is, an elemental Re/Os ratio of ~25. Thus the continental crustal Os concentration (Table 2) yields a Re concentration range between 1.25 and 2 ng Re g^{-1}.

An independent estimate of the Re concentration of the continental crust can be obtained by using its close relationship to Mo in crustal rocks. This is most obviously seen in the high concentrations of Re in molybdenites[21]. Newsom and Palme[22] have estimated that the Mo concentration of the upper mantle is 0.059 μg Mo g^{-1}. Chou *et al.*[15], using a slightly different

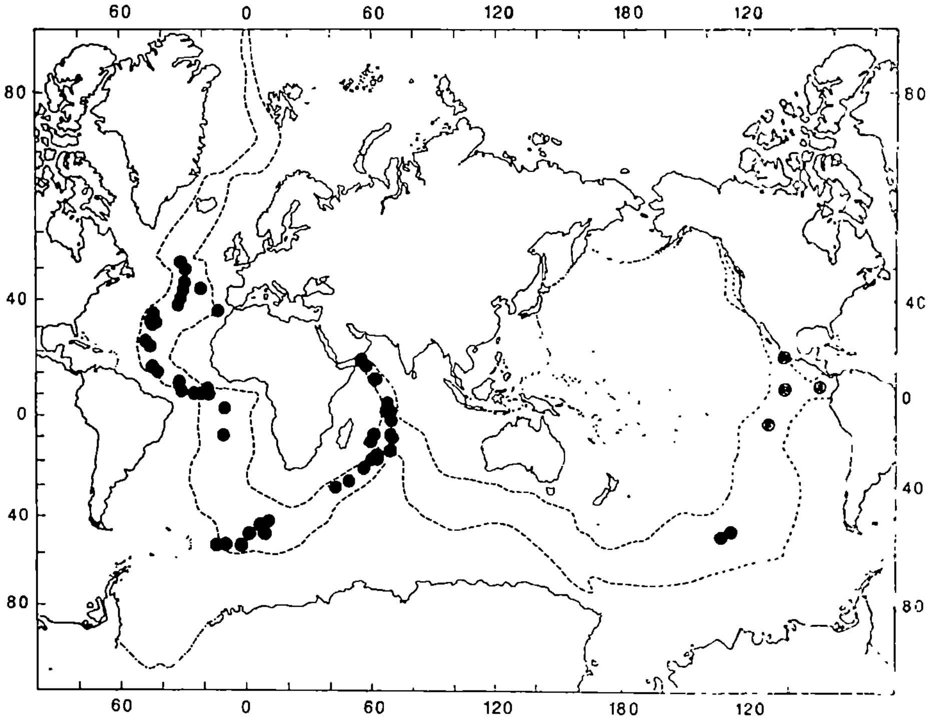

Fig. 2 Distribution of peridotites recovered from fracture zones at mid-ocean ridges[16-19].

method arrive at a Re concentration in the upper mantle of 0.25 ng Re g^{-1}. This yields a Re/Mo ratio of 0.0042. Estimates of the Mo concentrations of the continental crust range between 1 and 1.5 μg Mo g^{-1} (see ref. 23 for a summary). An average value of 1.3 μg Mo g^{-1} gives a continental crustal Re concentration of 5.5 ng Re g^{-1}, assuming no fractionation between mantle and crust. If this is correct, then the Os concentration of the continental crust, based on a $^{187}Os/^{186}Os$ ratio of 30 and a Re/Os ratio of 25 (see above), would be 0.22 ng Os g^{-1}. This value is much higher than the value of 0.08 based on the Ir concentrations discussed above.

Assuming the Re/Mo ratio of the mantle determined from the data of Chou *et al.*[15] and Newsom and Palme[22] is correct, it is more likely that fractionation of Re and Mo during the formation of the crust from the mantle has resulted in a crustal Re/Mo ratio that is one-third that of the mantle.

Turekian and Luck[6] used a simple model of weathering to explain the crustal $^{187}Os/^{186}Os$ ratio calculated for the Atlantic and Pacific basins. The difference between the Atlantic and Pacific Os and Nd isotopic signatures requires an ultramafic source to contribute Os more efficiently to the Atlantic Ocean than the Pacific Ocean. We have reaffirmed that the differences are due to the alteration of ultramafic rocks uniquely present within the Atlantic Ocean basin. We have assumed that all the continents yield the same $^{187}Os/^{186}Os$ ratio. Turekian and Luck[6] allowed for the possibility that the 'ultramafic' to 'granite' ratio could vary between the continents and, therefore, the $^{187}Os/^{186}Os$ ratio of the continents could differ. This mechanism is not required if, as has been demonstrated here, the internal ocean basin imprints are significant and vary between the Atlantic and Pacific.

We can continue to use their model to calculate the relative proportions of 'ultramafic' and 'granitic' rocks that are undergoing weathering worldwide. The model partitions the continental crust into an 'ultramafic' component with $^{187}Os/^{186}Os = 1$ and a purely radiogenic ^{187}Os component associated with high Re-bearing mineral phases of 'granitic' rocks. These Re-bearing minerals are probably those rich in Mo, most notably molybdenite[21].

The amounts of 'granitic' and 'ultramafic' rocks undergoing weathering are designated A_G and A_U, respectively; the continental crustal $^{187}Os/^{186}Os = 30$ and ultramafic rock $^{187}Os/^{186}Os = 1$; the Os concentration of ultramafic rock is 5 ng Os g^{-1} (refs 7, 15); the mean age of the continents is 2×10^9 yr; $[^{187}Os]_G = [^{187}Re]_G \lambda t$. With these parameters we can determine the relationship between the concentration of Re in the 'granitic' crust and the ratio of 'ultramafic' to 'granitic' rocks being weathered (A_U/A_G). For the 'ultramafic' contribution we get:

$$[^{187}Os]_U = 0.016[Os]_U = 0.016 \times 5 \text{ ng } ^{187}Os \text{ g}^{-1}$$
$$= 0.08 \text{ ng } ^{187}Os \text{ g}^{-1}$$

and for the 'granitic' contribution we get:

$$[^{187}Os]_G = 0.63[Re]_G \lambda t$$
$$= [Re]_G \times 0.63 \times 1.52 \times 10^{-11} \text{ yr}^{-1} \times 2 \times 10^9 \text{ yr}$$

(0.016 and 0.63 are the fractions of ^{186}Os and ^{186}Re in Os and Re respectively).

The relationship between $[Re]_G$ and A_U/A_G in these conditions (assuming total dissolution during weathering) is:

$$[Re]_G = 121.4 \, A_U/A_G$$

If $[Re]_G = 2.0$ then $A_U/A_G = 0.0165$, a value close to Daly's[24] estimate of the relative proportions of 'ultramafic' and 'granitic' rocks in the continental crust. To obtain A_U/A_G close to Knopf's[25] estimate (0.0025) requires $[Re]_G$ to be an order of magnitude lower than the value used here.

We thank J. M. Luck and N. Shimizu for technical help, D. J. Piepgras, S. L. Goldstein and S. E. Calvert for donating samples, and S. R. Hart for permission to use the SIMS ion probe at MIT. M. Lindner of the Lawrence Livermore National Laboratory made and provided us with ^{185}Os tracer. This research was funded by NSF grant OCE-8414753. M.R.P. acknowledges the partial support of a NATO fellowship. We thank R. K. O'Nions for comments.

Protein kinase C activation induces conductance changes in *Hermissenda* photoreceptors like those seen in associative learning

J. Farley* & S. Auerbach†

Phosphorylation of ion channels has been suggested as one molecular mechanism responsible for learning-produced long-term changes in neuronal excitability[1]. Persistent training-produced changes in two distinct K$^+$ currents (I_A (ref. 2), $I_{K\text{-}Ca}$ (refs 3, 4)) and a voltage-dependent calcium current (I_{Ca}; refs 3, 4) have previously been shown to occur in type B photoreceptors of *Hermissenda*, as a result of associative learning. But the identity of the phosphorylation pathway(s) responsible for these changes has not as yet been determined. Injections of cyclic AMP-dependent protein kinase[5] reduce a K$^+$ current (I_K) in B cells which is different from those changed by training, but fails to reduce I_A and $I_{K\text{-}Ca}$. Phosphorylase *b* kinase (an exogenous calcium/calmodulin-dependent kinase) reduces I_A[6], but whether $I_{K\text{-}Ca}$ and I_{Ca} are changed in the manner of associative training is not yet known. Another protein kinase present in high concentrations in both mammalian brain and molluscan nervous systems is protein kinase C[7,8], which is both calcium- and phospholipid-sensitive[9,10]. We now present evidence that activation of protein kinase C by the tumour promoter phorbol ester (PDB) and intracellular injection of the enzyme induce conductance changes similar to those caused by associative training in *Hermissenda* B cells (that is a reduction of I_A and $I_{K\text{-}Ca}$, and enhancement of I_{Ca}). These results represent the first direct demonstration that protein kinase C affects membrane K$^+$ ion conductance mechanisms.

Hermissenda's phototaxic behaviour is suppressed when light stimuli are presented in association with rotation (an unconditioned noxious stimulus)[11,12]. Long-lasting changes in the neural excitability of the B photoreceptors underlie this associative learning[13,14]. The persistent changes in B photoreceptor excitability include an enhancement of the cells' steady-state depolarizing light response and a decrease in resting membrane conductance[14,15]. These, in turn, arise from training-produced reductions in a transient voltage-dependent K$^+$ current (I_A[2]), a delayed calcium-activated K$^+$ current ($I_{K\text{-}Ca}$[3,4,16]) and enhancement of a slow voltage-dependent calcium current (I_{Ca}[3,4]). Previously, it was suggested that the long-term K$^+$ current changes were due to a calcium/calmodulin-mediated phosphorylation process[6], stimulated by pairing-specific increases in intracellular calcium levels arising from enhanced calcium influx during the acquisition phase of associative learning[17]. No mechanism for training-produced changes in I_{Ca} in B cells has been previously proposed or demonstrated.

In B cells, exogenous application of serotonin (10^{-5} M), an endogenous neurotransmitter present within the optic ganglia near photoreceptor fine processes and released during associative training[18], produces the same changes of conductance and of light response as associative training[19].

The membrane-soluble tumour promoter 4β-phorbol 12β,13α-dibutyrate ester (PDB), an activator of protein kinase C[20], consistently enhanced the steady-state depolarizing response of type B photoreceptors produced by light when present in concentrations of 1-10 nM (Fig. 1) and decreased the resting membrane conductance (Table 1). These effects were observed within 1-2 min in every cell examined ($n = 23$) and persisted for the duration of recording (~1 h) even when followed by extensive washing. Inactive forms of the ester (4α-phorbol) as well as solvent application (10^{-6}% acetone, v/v) had no effect. Pretreatment of B cells with 10^{-5} M serotonin enhanced the steady-state light response and decreased the resting membrane conductance, as reported previously[19], and diminished the effect of PDB on B cells (Table 1).

Iontophoretic injections of protein kinase C (PKC) mimicked the effects of PDB, serotonin and associative training. PKC enhanced the magnitude of the light response and decreased net membrane conductance in all 13 B cells tested (Fig. 1, Table 1). As was the case for PDB, these effects were extremely persistent, lasting for the duration of recording (~1 h). Iontophoretic injections of heat-inactivated PKC ($n = 10$), buffer ($n = 5$), or material from a non-PKC peak eluting from the DEAE-cellulose column ($n = 3$) were all without effect.

Previous research has determined that the light response of the type B photoreceptor arises from the combined effects of light-, voltage- and calcium-activated ionic currents. Two distinct light-gated currents have been identified: (1) a transient, inward Na$^+$ current[21] ($I_{Na\text{-}light}$), which is tetrodotoxin-insensitive, voltage-independent, and underlies the rapid depolarizing limb of the light-induced generator potential and (2) a slower inward current which reflects both a cation-nonspecific conductance increase (J.F., unpublished observations) as well as a light-mediated reduction in a resting K$^+$ conductance[22]. Three voltage-dependent currents have been described: (1) I_A[23], a transient, rapidly inactivating, 4-aminopyridine (4-AP)-sensitive K$^+$ current which is reduced by both associative training[2] and intracellular calcium load[24]. In contrast to 'A' currents seen in other gastropod neurones[25,26], I_A in *Hermissenda* B cells is activated at membrane potentials near the resting potential of the cell (−50 to −60 mV) and is half-inactivated at a steady-state membrane potential of ~ −45 mV[23]. In contrast, half-maximal inactivation in both dorid[25] and *Tritonia*[26] neurones occurs at a considerably more negative membrane potential (−70 to −75 mV). (2) I_K, a delayed, sustained, tetraethylammonium (TEA)-sensitive outward K$^+$ current observed in many neurone somata[27], and (3) I_{Ca}, a small voltage-sensitive inward calcium current[28]. Also present in B cells is a calcium-activated K$^+$ current ($I_{K\text{-}Ca}$)[3,4,28] which resists block by extracellular TEA and 4-AP, contributes to the steady-state depolarizing light response, and is reduced by associative training[3,4]. We have examined each of these currents to determine which are affected by PDB and PKC.

Under voltage-clamp control, nanomolar concentrations of PDB reduced the fast, rapidly inactivating K$^+$ current (I_A) in each of 12 B cells (Fig. 2, Table 1). In eight of these cells PDB application also resulted in a hyperpolarizing shift in the voltage-dependence of inactivation of ~6-8 mV and a more modest shift of 3-4 mV in the voltage-dependence of activation. Because

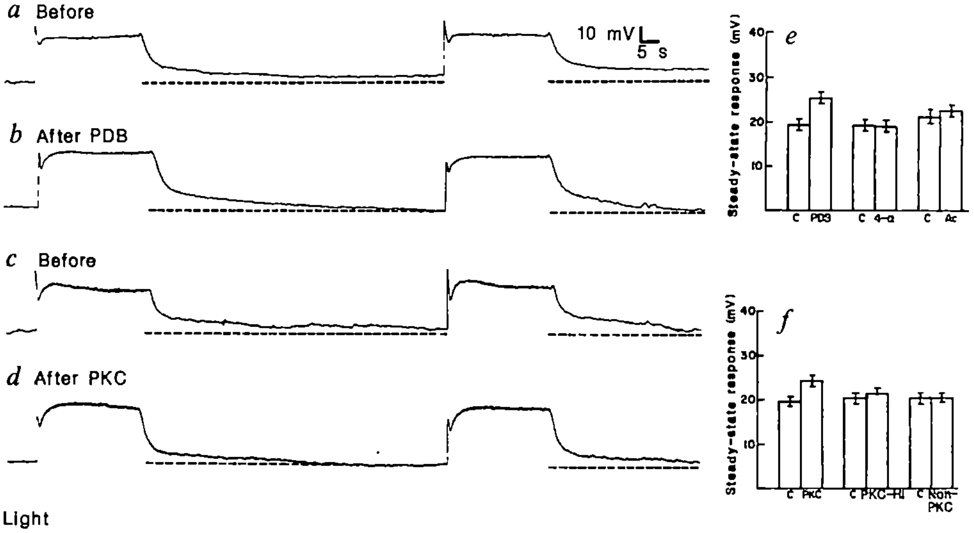

Fig. 1 PDB and PKC enhance the steady-state depolarizing light response of type B photoreceptors. Type B cells were prepared for recording as in previous studies[2-6] and were ligated so as to remove action- and synaptic-potential-generating areas of the cell. Intracellular recordings were made with a single glass microelectrode (10–30 MΩ, 3 M KCl) connected to a bridge circuit for current injection. Light-evoked depolarizing generator potentials were elicited by 30-s presentations of a 4.0×10^{-4} W cm^{-2} (at 510 nM) light step every 2 min. ***a***, Light-induced B-cell response before PDB, in standard artificial sea water (ASW). ***b***, Effect of PDB (2 min after bath application). PDB (Sigma) was diluted with acetone to make a 5 mg ml^{-1} stock which was stored frozen at −20 °C. The stock was diluted with ASW on the day of the experiment. Final concentrations of PDB and acetone in the bath were $1\text{–}10\times10^{-9}$ M and 10^{-6}% (v/v), respectively. Application of solvent alone, or inactive forms of the phorbol ester (4α-phorbol) had no effect. PDB enhanced the steady-state component of the light response. ***c***, Light-induced B-cell response in ASW, prior to PKC injection. ***d***, Effect of PKC (2 min post-injection). A single 30-s injection of PKC enhanced the steady-state light response of the B cells; a modest reduction of the initial transient depolarizing limb of the generator potential was also often observed. ***e***, Summary of data obtained from 23 cells exposed to PDB, 5 cells exposed to acetone solvent (Ac), and 11 cells exposed to 4α-phorbol (4-α) (C = control). Measurements of the steady-state light-response amplitude were taken at 25 s after light onset and are averages from the three light presentations prior to, and 2 min after, application. ***f***, Summary of data from 13 cells exposed to PKC injections, 10 cells exposed to heat-inactivated PKC injections (PKC-HI), and 8 cells exposed to either buffer alone ($n = 5$; not shown) or injections of a non-PKC peak eluting from the DEAE-cellulose column ($n = 3$, non-PKC). Only PKC injections produced an enhancement of the B cells' light response. All other treatments had no effect. Protein kinase C was partially purified from rat brain using the procedure of Niedel *et al.*[35], by ammonium sulphate precipitation and chromatography on a DEAE-cellulose column. The DEAE-cellulose column was washed with 10 ml of the equilibration buffer (20 mM Tris-HCl, *p*H 7.5/50 mM 2-mercaptoethanol), then a 60-ml linear gradient of 0–0.6 M NaCl in equilibration buffer was applied. The protein peak eluting at 0.3–0.4 M NaCl contained protein kinase C activity, as demonstrated by incorporation of ^{32}P from [γ-^{32}P]ATP into histone type III-S and ^{3}H-phorbol diester binding. With incubation conditions as described previously[36], in the presence of both Ca^{2+} and phospholipids, enzyme activity resulted in transfer of 54 pM of phosphate per min per mg protein. In the absence of either Ca^{2+} or diacylglycerol, no activity could be detected. Thus, the enzyme was injected in a largely inactive form. The electrode tip was filled via capillary action with PKC in a 20 mM Tris-HCl/350 mM NaCl solution (*p*H = 7.5). Protein kinase C was iontophoresed as an anion using 1–3 consecutive 15–30-s pulses of anodal (1.0–3.0 nA) current, resulting in the ejection of PKC quantities capable of producing 5×10^{-8} units of activity[9]. A small constant (+0.05 nA) cathodal brake current was applied to prevent leakage of PKC before and after each injection.

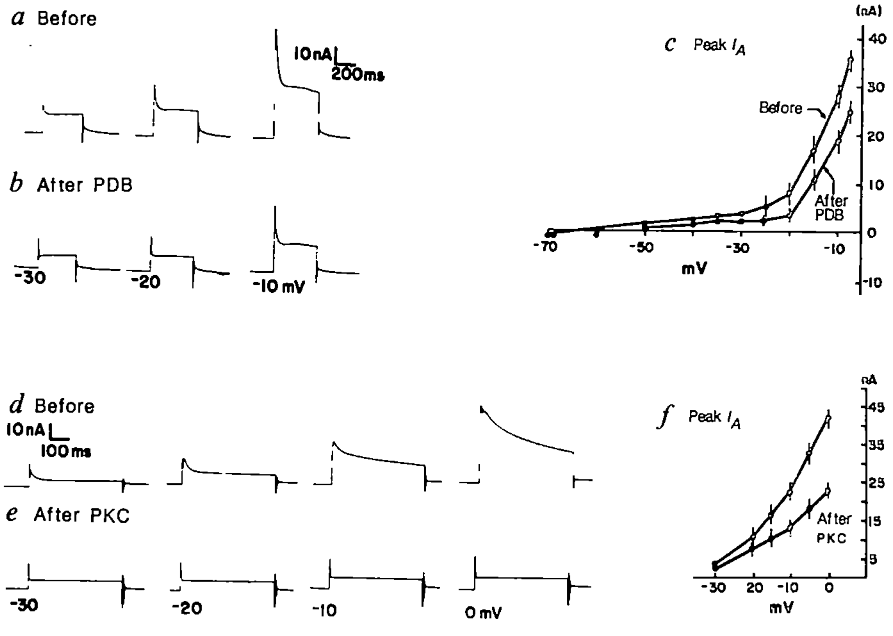

Fig. 2 PDB and PKC reduce I_A. ***a***, Outward current records elicited by command steps to potentials more positive than −30 mV in standard ASW exhibit an early (20–50 ms) transient peak (I_A) which then decays to a smaller sustained level of current (comprised of both I_K and $I_{K\text{-Ca}}$). Holding potential (V_h) was −60 mV. Records were obtained before addition of PDB. ***b***, Transient peak A current amplitude was reduced by 10^{-9} M bath-applied PDB, as was the steady-state outward current. Records obtained 2 min after PDB application. ***c***, Effects of PDB on I_A, averaged for 12 cells. Each data point in the *I–V* plot represents the average of four or five measurements of transient peak current (absolute amplitude corrected for leakage) at the indicated membrane potentials. Steps were presented at frequencies sufficiently low to preclude any slow-inactivation[37] contamination (once per 30 s). ***d***, Fast, rapidly inactivating K^{+} currents elicited in ASW from a holding potential of −60 mV before PKC injections. ***e***, A currents were reduced by a single 30-s (−3.0-nA anodal current) injection of PKC. Records obtained 5 min after PKC injection. ***f***, Average effect of PKC on I_A currents for 10 cells. Error bars represent 1 s.e.m.

Methods. Single synaptically isolated medial and intermediate type B photoreceptors were obtained from the eyes of adult untrained *Hermissenda* by enzymatic treatment with protease (Sigma Type VII) and ligature effected by a razor lesion of the optic nerve. In intracellular microelectrode (3 M KCl, 10–20 MΩ) recording studies (Fig. 1), B cells were characterized by resting potentials > −45 mV, membrane resistance >25 MΩ, peak and steady-state light-induced (4×10^{-4} W cm^{-2} at 510 nM) generator potentials of >25 and >20 mV, respectively, after 6 min of dark adaptation. Two-electrode voltage-clamp methods for the B-cell soma have been extensively described elsewhere[2-6] (3 M KCl electrodes, ~6 MΩ for current electrode; 10–20 MΩ for the voltage electrode). Space-clamp control was more than adequate, as judged by the ability to clamp the light-induced generator currents arising on the rhabdomere. In three experiments the cell's isopotentiality was confirmed by inserting a third electrode some distance away from the voltage-recording and current-passing electrode. Membrane potential settling time was 0.2–1.0 ms for all experiments reported. When impaled with two electrodes, cells either satisfied the following criteria or were discarded: (1) resting potential (V_m) > −40 mV; (2) equivalent resting (±2 mV) and light-induced (peak) generator potentials (>20 mV) as recorded through current and voltage electrodes; (3) holding currents in ASW ($V_h = -60$ mV) < −2.0 nA. The standard bathing fluid (ASW), unless otherwise noted, was (in mM): 430 Na^{+}, 10 K^{+}, 10 Ca^{2+}, 50 Mg^{2+}, 10 Tris, 570 Cl^{-} (*p*H = 7.6). All experiments were done at room temperature (20 °C). All reported current values for Figs 1–3 were corrected for leakage current by extrapolation from a linear portion of the current–voltage relation (10, 20-mV steps from $V_h = -60$ mV).

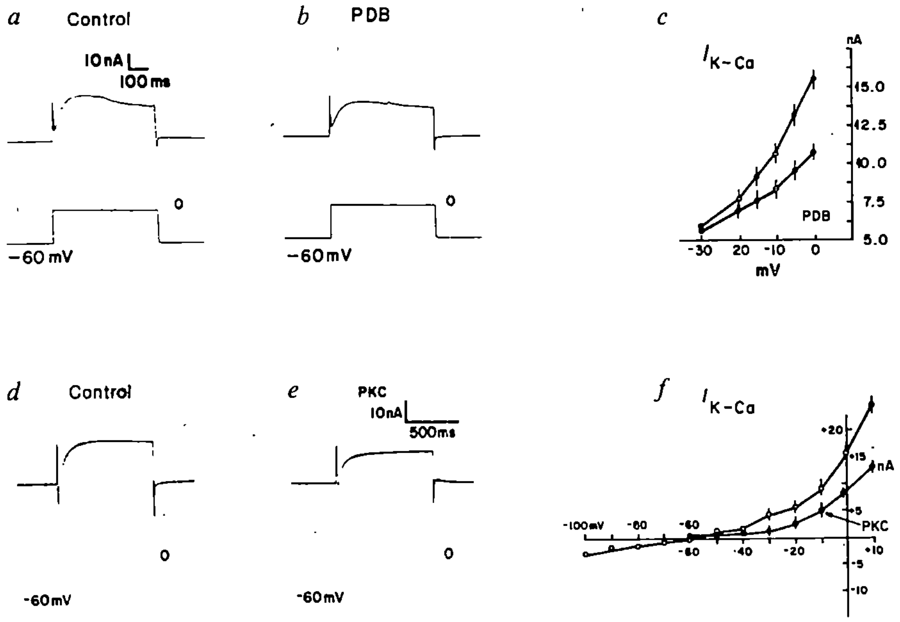

Fig. 3 PDB and PKC reduce $I_{K\text{-}Ca}$. *a*, $I_{K\text{-}Ca}$ measured at 0 mV before PDB application. $I_{K\text{-}Ca}$ was isolated using 5 mM 4-AP (Sigma) and 100 mM TEA (Aldrich) to block other voltage-dependent K^+ currents[28]. *b*, PDB reduces $I_{K\text{-}Ca}$. Measurements taken 5 min after bath application of PDB (1×10^{-9} M). Initially, PDB resulted in a slight enhancement of $I_{K\text{-}Ca}$ which lasted for 0.5–1.5 min (not shown). *c*, Average PDB effects for 10 cells, 5 min post-PDB (see also Table 1). *d*, $I_{K\text{-}Ca}$ measured before PKC injection. *e*, PKC injection reduced $I_{K\text{-}Ca}$; measurements taken 1.5 min after the PKC injection. *f*, Average results for 8 cells (see also Table 1), 1.5 min post-PKC injection. Error bars, 1 s.e.m.

reduction of I_A by PDB was near-maximal (>90%) in the remaining four preparations, and could not be overcome by steps to more positive potentials or by holding at more negative potentials, it is unlikely that the changes in voltage-dependence account completely for the reduction in the macroscopic current but rather appear to be an additional effect. Bath application of PDB also resulted in a biphasic modulation of $I_{K\text{-}Ca}$. The initial effect (1–3 min) was to enhance $I_{K\text{-}Ca}$; this was followed, however, by persistent reductions of 20–63% in the current (Fig. 3, Table 1).

The sole voltage-dependent inward current (I_{Ca}) present in B cells is carried by calcium ions[28]. I_{Ca} is increased by serotonin[19] as well as by associative training[3,4]. PDB application increased I_{Ca} in the nine cells examined (Fig. 4, Table 1), without obvious effect on the kinetics or voltage-dependence of activation or inactivation. Similar effects on I_{Ca} of *Aplysia* bag-cell neurones by a phorbol ester (tetradecanoyl phorbol 13-acetate) and protein kinase C were described recently by DeRiemer *et al.*[29].

Under voltage-clamp control, iontophoretic injections of PKC reduced I_A (Fig. 2, Table 1) and $I_{K\text{-}Ca}$ (Fig. 3, Table 1), and enhanced I_{Ca} (Fig. 4, Table 1). Pretreatment of B cells with serotonin reduced these effects of PKC (Table 1). At bath concentration of 1–10 nM, imipramine, which has been reported to inhibit PKC activation[30], blocked the enhancement of the B

cell's light response and the decrease in conductance caused by PDB and PKC.

These data indicate that activation of protein kinase C in *Hermissenda* B cells can lead to reductions in both voltage- and calcium-activated potassium currents, and enhancement of a voltage-dependent calcium current. The net effect of these conductance changes is an enhancement of the B cell's depolarizing light response and a decrease in resting membrane conductance. Because these effects of PKC are essentially identical to those produced by associative training of the animal, which in turn are mimicked by serotonin application, it is attractive to suppose that serotonin-induced PKC activation is one mechanism by which long-term excitability changes in B cells arise from associative training. It is a mechanism which may be distinct from the previously proposed calcium/calmodulin-dependent phosphorylation pathway. Although PKC does require calcium for full activity, data from cell-free enzymatic reaction systems indicate this requirement to be a biochemical rather than a physiological one[8]. In blood platelets 10^{-7} M free calcium has a maximal and saturating effect on PKC activity[9]. Free calcium levels in nerve and neurones are typically already 10^{-7} M[11], which would be expected to confer a relative independence of PKC from physiological changes in intracellular calcium levels.

Although molecularly distinct, calcium-calmodulin-dependent and PKC-dependent phosphorylation may act in a synergistic fashion to effect long-term current changes in B cells. I_A[24] and $I_{K\text{-}Ca}$[22] in *Hermissenda* B cells are reduced by large increases in the intracellular calcium concentration. Illumination of B cells leads to the release of calcium from intracellular stores in B cells[17,22], and may thereby transiently reduce I_A and $I_{K\text{-}Ca}$. In other tissues[32], serotonin can lead to mobilization of intracellular calcium, mediated by inositol trisphosphate[33], in addition to its activation of PKC. Thus, it is possible that light and serotonin may act in a synergistic manner in their activation of both protein kinase C and calcium-calmodulin-dependent protein kinase in the B cell. In future studies it will be important to determine whether the effects of PDB and PKC on the ionic conductances are direct, representing PKC-dependent phosphorylation of ionic channels, or indirect, perhaps through an interaction with calcium/calmodulin or cyclic nucleotide pathways (as has been demonstrated in oocytes[34]).

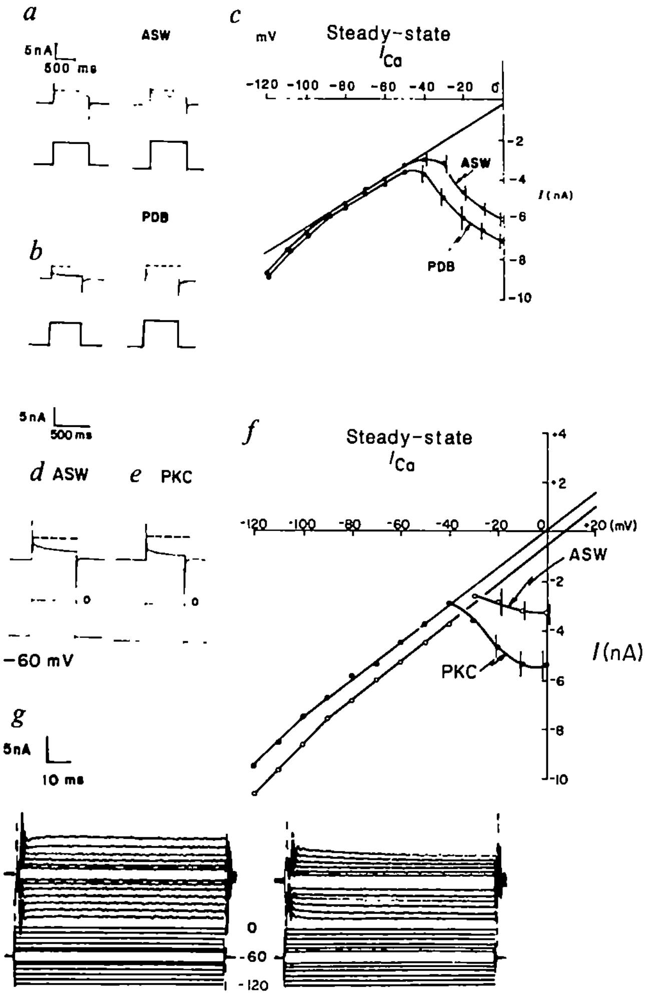

Fig. 4 PDB and PKC enhance I_{Ca}. ***a***, I_{Ca} measured at −10 and 0 mV, respectively, before PDB application. I_{Ca} was isolated using 5 mM 4-AP, 100 mM TEA, 10 mM Ba_0^{2+} for Ca_0^{2+}, and 300 mM K_0^+. In these conditions[28], $E_K = \pm 2$ mV. Thus, measurements of the inward current at 0 mV are uncontaminated by any residual K^+ conductance[28]. Extrapolated leak-current values are denoted by the dotted line. ***b***, I_{Ca} measured 2 min after application of 10^{-9} M PDB. I_{Ca} was enhanced. PDB did not result in any change in holding current, however, indicating that it largely affected the voltage-dependent conductance. Leak currents were unaffected. ***c***, Average results for nine cells (see also Table 1). Values are for total membrane current. ***d***, I_{Ca} measured at 0 mV prior to PKC injection. ***e***, PKC injection enhanced I_{Ca} (record obtained 2 min after injection). ***f***, Average results for 7 cells (see also Table 1). Values are for total membrane current. PKC injections enhanced I_{Ca} at all potentials more positive than −30 mV. Error bars, 1 s.e.m. ***g***, Enhanced inward current is not sodium-dependent. In previous work[28], the possibility that Na^+ influx might contribute to the inward current was not directly addressed. Consequently, in further experiments sodium chloride was replaced in Na-free saline by substituting tetramethylammonium chloride (TMA, $n = 6$) or trizma base ($n = 3$) in equimolar concentrations. These substitutions had no effect on the magnitude or kinetics of the inward current, measured in either the presence or absence of PKC injections, except that with prolonged exposure to 0 Na saline, the cells became rather leaky. Shown here is the inward current measured in TMA-ASW before (left) and after (right) PKC injection.

During development of the female mouse embryo, one of the two X chromosomes is inactivated in a random manner in most cell lineages[1]. However, in the extraembryonic trophectoderm and primary endoderm lineages there is preferential inactivation of the paternally derived X chromosome[2–4]. The inactivated X chromosomes of the extraembryonic and somatic tissues appear equally inactive at the level of the expression of X-linked genes[2–7]. However, there are differences in the timing of their replication[8–10] and the extent of DNA modification as determined by gene transfer[11–15]. The identification of transgenic animals carrying X-linked modified α-fetoprotein (AFP) genes allowed us to examine whether the inactivation process extends to an autosomal gene which is normally expressed at high levels in specific extraembryonic and somatic cells, and if so, whether the inactivation process is different in these two tissues. Our results demonstrate that the X-linked AFP genes were expressed on the inactive X chromosome in the visceral endoderm of the yolk sac but not in fetal liver. Thus, the transcriptional activity of the AFP minigene on the inactive X chromosome is dependent on the tissue in which it resides, and most probably reflects differences in the nature of the maintenance of the inactive state of the extraembryonic and embryonic X chromosomes.

We have shown previously that transgenic mice carrying exogenous AFP genes express these genes in a tissue-specific and temporally appropriate manner in the visceral endoderm of the yolk sac, the fetal liver and the fetal gastrointestinal tract[16]. During breeeding experiments with one line derived from a male F_1 of the founder mouse, 47-3, we observed that the two to three tandem copies of the AFP minigene were segregating with the X chromosome. In analysing more than 1,200 progeny derived from five F_1 transgenic males, all females and no males carried the AFP minigenes. In contrast, females were able to transmit the genes equally to females and males. A partial pedigree is shown in Fig. 1.

To determine whether the AFP minigenes on the paternally derived X chromosome were preferentially inactivated in the visceral endoderm of the yolk sac, a tissue in which AFP messenger RNA constitutes 20% of the mRNA pool, animals were obtained by caesarean section at 14–16 days of fetal development from matings between $(C57Bl/6\times SJL)F_1$ mice with either male or female transgenic mice. Transgenic fetuses were identified by hybridizing fetal liver genomic DNA to a first exon-specific AFP probe able to detect both the endogenous and the introduced AFP genes[16,17]. The sex of the fetuses was determined by hybridization of genomic DNA to a retroviral probe (M270) that can detect sequences on the Y chromosome[18] (data not shown).

Total yolk sac poly(A)$^+$ RNA from female transgenic progeny was isolated, fractionated by electrophoresis and hybridized to an AFP probe. The introduced AFP minigene is an internally deleted AFP gene[16,17] that generates a correctly initiated and processed 600-nucleotide poly(A)$^+$ RNA readily distinguished

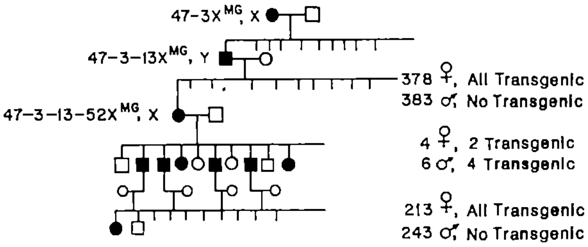

Fig. 1 Simplified pedigree of the 47-3-13 line showing segregation of the X-linked AFP minigenes. The founder mouse (47-3) was mated to $(C57BL/6\times SJL)F_1$ males and one of her male progeny (47-3-13) was mated to BALB/cJ mice. The sex of all subsequent progeny was determined by external genitalia and/or tail DNA analysis[16] using the retroviral probe (M720) which is able to detect sequences on the Y chromosome[18]. Males are indicated by squares and females by circles. Transgenic animals (closed symbols) were identified with an AFP hybridization probe in the manner shown in Fig. 4*b*. MG refers to the AFP minigene.

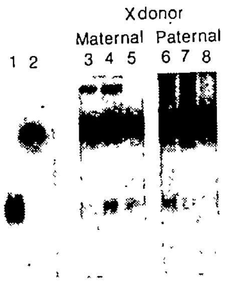

Fig. 2 Expression in yolk sac of the AFP minigenes located on the inactive paternal or active maternal X chromosome. Lanes 1 and 2 are control RNAs denoting the migration of AFP minigene (lane 1) and authentic AFP mRNA (lane 2). Transgenic females or males were mated to $(C57BL/6\times SJL)F_1$ animals, and transgenic female progeny were identified on days 14–16 post-fertilization by hybridization of fetal liver and yolk sac DNAs, isolated according to published procedures[16], to AFP- and Y-chromosome[18]-specific sequences. Poly(A)$^+$ RNA was isolated from individual yolk sacs of progeny derived from transgenic females (lanes 3–5) and males (lanes 6–8), fractionated on denaturing formaldehyde 1.7% agarose gels and transferred to nitrocellulose. The RNAs were hybridized to an AFP-specific single-stranded RNA probe as detailed previously[16].

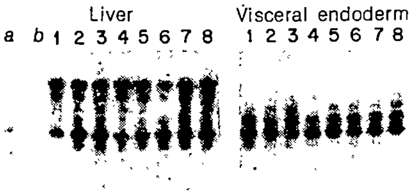

Fig. 3 Differential expression of HPRT isozymes in the yolk sac and liver of transgenic females. The pattern of expression of HPRT isozymes in eight transgenic female livers (lanes 1–8, left) and visceral endoderms (right) was determined. Lanes *a* and *b* are control samples for the HPRT-A and HPRT-B isozymes, respectively. Male transgenic animals carrying the *pgk*-1^b and *hprt*^{b} alleles were mated to C3H/He female congenic mice heterozygous for the *pgk*-$1^{a/b}$ and *hprt*$^{a/b}$ alleles. Fetuses were obtained by caesarian section at 14–16 days' gestation and the livers and yolk sacs removed. The visceral endoderm of the yolk sac was separated from the mesodermal layer by incubating the tissue in an enzyme mixture (2.5% pancreatin, 0.5% trypsin, 1 × pucks saline A) at 4 °C for 1 h as described previously[5–7,9,15,28]. The tissue was transferred to phosphate-buffered saline at 4 °C and the layers were separated with forceps under a dissecting microscope. In some cases DNA and RNA were isolated from the tissues and analysed, and in others HPRT and PGK isozyme analysis was performed as described previously[12,15,19,20]. Only progeny which exhibited the informative *hprt*$^{a/b}$ and *pgk*-$1^{a/b}$ genotype (16/97) are shown.

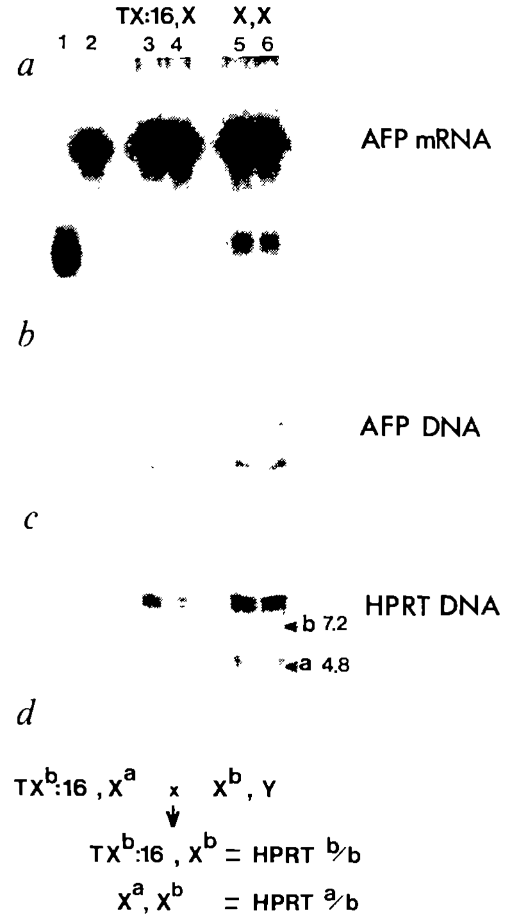

Fig. 4 Expression of the X-linked AFP minigenes in the livers of animals bearing the Searle's translocation. *a*, Poly(A)$^+$ RNA was isolated from day 1 neonatal animals and analysed after gel electrophoresis by hybridization to an AFP-specific probe. Lane 1 is a control for the migration of the minigene mRNA and lane 2 is a control RNA isolated from a non-transgenic animal. Lanes 3 and 4 are from two transgenic animals carrying the Searle's translocation and lanes 5 and 6 from two normal XX transgenic littermates. *b*, Hybridization of genomic DNA isolated from livers of the same animals as in *a* to an AFP-specific probe. The faster-migrating band indicates the presence of the X-linked minigene in lanes 3–6. *c*, Hybridization of the same genomic DNA in lanes 3–6 with an *hprt* cDNA probe that distinguishes between the *hprt*^{a} and *hprt*^{b} alleles. *d*, A diagramamatic representation of the mating and predicted genotypes of the female offspring.

Methods. Female mice carrying Searle's translocation[21] have the *pgk*-1^b and *hprt*^{b} alleles on the translocated portion of the X chromosome, and the *pgk*-1^a and *hprt*^{a} alleles on the normal X chromosome. These animals were mated to transgenic males carrying the X-linked *hprt*^{b} and *pgk*-1^b alleles and the AFP minigenes. Progeny were killed on day 1 of neonatal life and RNA and DNA were isolated from the liver as described previously[16]. The DNA samples (10 μg) were restricted with *Hin*dIII, electrophoresed through a 1% agarose gel, transferred to nitrocellulose and hybridized with either a nick-translated AFP probe or an *hprt* cDNA probe as described elsewhere[16]. The 4.8-kb *Hin*dIII fragment is a restriction fragment length polymorphism associated with the *hprt*^{a} allele used in this cross (F. Berger and V.M.C., unpublished results). It is present on the intact X chromosome of the t(X; 16H) dam of these offspring. Thus *hprt*$^{a/b}$ progeny are X/X while *hprt*^{b} progeny are probably t(X; 16H) since *hprt* maps within 5 centimorgans of the translocation breakpoint. The poly(A)$^+$ RNA samples (~1 μg) were fractionated by electrophoresis through a denaturing formaldehyde agarose gel, transferred to nitrocellulose and hybridized with a single-stranded AFP probe as described previously[16].

from the 2.2-kilobase (kb) endogenous mRNA. Figure 2 shows that the AFP minigenes were expressed in the extraembryonic yolk sac, irrespective of whether they derived from the paternal (inactive) or maternal (active) X chromosome. Partial paternal X inactivation was suggested by a general two- to three-fold higher level of expression from the AFP minigenes when they were present on the maternally derived X chromosome.

To ensure that the paternal X chromosome was actually inactivated, male transgenic animals carrying the X-linked phosphoglycerate kinase-B (*pgk*-1^b) and hypoxanthine phosphoribosyl transerase-B (*hprt*^{b}) alleles were mated to C3H/He female congenic mice carrying the *pgk*-1^a and *hprt*^{a} alleles derived from wild mice[19,20]. Fetuses were collected at 14–16 days of gestation and the visceral endoderm of the yolk sac was isolated by dissection following enzymatic digestion[5,7,9,15]. Assays to distinguish the PGK and HPRT isoenzyme[15,19,20] and to quantitate AFP minigene mRNA were performed on both fetal liver and visceral endoderm samples. For eight of the appropriate females, both the A and B isozymes of HPRT were expressed in liver, whereas only the A isozyme from the maternally derived X chromosome was expressed in the visceral endoderm of the same animals (Fig. 3). Similar results were obtained for PGK (data not shown). However, as before, the AFP minigenes were expressed irrespective of their origin. Therefore, the ability of the minigenes to escape X-chromosome inactivation cannot be attributed to their presence interfering with the inactivation of the entire chromosome.

This experiment does not exclude the possibility that the AFP minigenes have integrated into a region of the X chromosome which normally escapes inactivation. On the other hand, the activity of X-linked AFP genes in the extraembryonic lineage could be a unique property of the X chromosome of that tissue. One way to distinguish between these possibilities is to examine the activity of the AFP minigenes on the inactive X chromosome in a somatic tissue, such as fetal liver. To do this we took advantage of a strain of mice carrying one copy of a balanced X: autosome translocation (t(X; 16H)) termed Searle's translocation[21]. In all females that carry the translocated X, the normal X chromosome donated by the male is inactive[5,7,10,12,15,22], presumably to prevent the partial monosomy of chromosome 16 that would otherwise occur. Thus, by crossing a transgenic male to a Searle's female, we will generate female progeny in which the X chromosome bearing the AFP minigene is inactive in all tissues. Normal XX females which will also result from this cross display random X inactivation and serve as controls. A diagrammatic representation of the mating and expected genotypes is shown in Fig. 4*d*.

Progeny were killed on day 1 of neonatal life and DNA and RNA were isolated from the liver, a tissue where AFP mRNA levels are ~10% of total poly(A)$^+$ mRNA. Transgenic animals were identified by DNA hybridization to an AFP probe (Fig. 4*b*) and normal XX females were distinguished from translocation-bearing females by using a restriction fragment length polymorphism that distinguishes between the *hprt*^{a} and *hprt*^{b} alleles (Fig. 4*c*). Analyses of AFP minigene expression in representative transgenic females are shown in Fig. 4*a*. The AFP minigenes were not expressed in liver on the inactive X of the females bearing the translocation, although expression was observed in normal XX littermates. Therefore, the transcriptional activity of the AFP minigenes on the inactive X chromosome is dependent on the tissue in which the chromosome resides.

The lack of expression of the minigenes on the inactive X chromosome in liver could be anticipated from studies on X chromosome: autosome translocations, where the inactive state extended past the breakpoint into the autosomal genes[23–25]. The surprising result is the continued expression in the visceral endoderm, which suggests that the inactivation mechanism can discriminate between an X-linked gene and an autosomal gene. This difference may not be a property of the X chromosome, but rather reflects differences in the modes of regulation of the

AFP gene itself in these tissues; for example, the concentration of critical transcription factors may be high enough in the visceral endoderm to gain access to the gene even on the inactive X.

Alternatively and more likely, these findings can be interpreted as support for the notion that there are functional differences between the inactive X chromosome in extraembryonic versus embryonic tissues. It has been argued that these differences reside at the level of the maintenance[12,15] rather than the establishment of inactivation, as by the criteria of gene activity both chromosomes are equally inactive. The X-linked AFP genes were partially inactivated (two–three-fold) on the paternal X in visceral endoderm, which is consistent with this idea.

One candidate to explain the differences between the two inactive chromosomes is differences in DNA modification, particularly methylation. This argument is based on gene transfer experiments which demonstrated that the activity of the *hprt* gene can be transferred to a recipient cell from the inactive X chromosome of embryonic origin after treatment of the cell with 5-azacytidine, unlike the extraembryonic derived *hprt* gene, which can be transferred without drug treatment. The genomes of the extraembryonic lineages in general are undermethylated relative to other somatic tissues[26,27], a condition that extends from structural genes independently of whether they are expressed to satellite DNA. Using the isoschizomers *Msp*I and *Hpa*II, which monitor the methylation status of a subset of CpG sites in the AFP minigene integration site, we have not detected any significant differences between the degrees of methylation of the locus on the inactive X in visceral endoderm and liver (data not shown). These experiments argue against global methylation differences as an explanation for continued expression of the minigenes on the visceral endoderm-derived inactive X chromosome.

In conclusion, the differential expression of the AFP minigenes on the inactive X chromosome in the visceral endoderm and liver suggests that the mechanism of maintenance of the inactive state is discriminating between normally X-linked genes and an autosomal gene in the former tissue but not in the latter.

We thank E. Eicher for providing the M720 probe, T. Caskey for the *hprt* cDNA probe, A. McLaren, M. Monk, B. Hogan and T. Vogt for valuable discussions and Marie Estes for the preparation of the manuscript. R.K. and R.E.H. were supported by NIH postdoctoral training grants CA09035 and HD07155, respectively. This work was also supported by NIH grants HD17321, GM24125, CA06927, CA28050 and RR05539 and an appropriation from the Commonwelath of Pennsylvania.

The *neu* oncogene encodes an epidermal growth factor receptor-related protein

Cornelia I. Bargmann, Mien-Chie Hung & Robert A. Weinberg

Whitehead Institute for Biomedical Research, 9 Cambridge Center,
Cambridge, Massachusetts 02142 and Department of Biology,
Massachusetts Institute of Technology, Cambridge,
Massachusetts 02139, USA

The *neu* oncogene is repeatedly activated in neuro- and glioblastomas derived by transplacental mutagenesis of the BDIX strain of rat with ethylnitrosourea[1]. Foci induced by the DNAs from such tumours on NIH 3T3 cells contain the *neu* oncogene and an associated phosphoprotein of relative molecular mass 185,000 (p185)[2]. Previous work has shown that the *neu* gene is related to, but distinct from, the gene encoding the EGF receptor (c-*erb-B*)[3,4]. Here we decribe a *neu* complementary DNA clone isolated from a cell line transformed by this oncogene; the clone has biological activity in a focus-forming assay. The nucleotide sequence of this clone predicts a 1,260-amino-acid transmembrane protein product similar in overall structure to the EGF receptor. We found that 50% of the predicted amino acids of *neu* and the EGF receptor are identical; >80% of the amino acids in the tyrosine kinase domain are identical. Our results suggest strongly that the *neu* gene encodes the receptor for an as yet unidentified growth factor.

Transcripts of the *neu* gene were identified in NIH 3T3 cells transformed by *neu*. Polyadenylated RNA was isolated from B104-1-1, an NIH 3T3-derived cell line transformed by DNA from the B104 rat neuroblastoma cell line and known to express a high level of p185 (ref. 2). RNA was also isolated from NIH 3T3 cells transformed by a *ras* oncogene and from Rat-1 cells, a rat fibroblast line which expresses a protein immunologically related to p185 (ref. 3). This protein, which is also of $M_r \sim$ 185,000, is probably the product of the normal allele of the *neu* gene. A Northern blot of these RNAs was probed with R4E, a 4-kilobase (kb) *Bam*HI clone isolated from a genomic rat liver library by hybridization with part of the v-*erb-B* oncogene. This clone corresponds to the putative kinase domain of the rat *neu* gene (data not shown).

Under stringent conditions, this probe hybridized with RNAs of 4.4, 5.0 and 9 kb present in the *neu*-transformed NIH 3T3 cell line that were not present in the *ras*-transformed cell line (Fig. 1*a*,*b*). The smaller of these RNAs appeared also to be present in Rat-1 cells (Fig. 1*c*). These data strongly suggest that these messenger RNAs are the transcripts derived from the rat *neu* gene present in B104-1-1 cells and not the endogenous mouse gene. Quantitation of RNA levels by hybridization with a single-stranded RNA probe specific for *neu* indicated that these *neu* transcripts represent between 0.01 and 0.05% of the polyadenylated RNA in B104-1-1 cells.

A cDNA library was prepared from B104-1-1 polyadenylated RNA using standard S_1 snapback techniques[5]. Nine recombinant plasmids reactive with a *neu* probe were isolated, eight of which were derived from the same family of mRNAs as determined by restriction mapping. The largest of these, designated neuc(t)34, had an insert of 4.8 kb and was used for all subsequent studies.

In Northern analysis this cDNA clone reacted with all three of the mRNAs detected by the genomic clone (data not shown) and with no additional transcripts. A 400-base pair (bp) fragment from the extreme 3′ end of neuc(t)34 was used as a probe on an identical Northern filter and, as shown in Fig. 1*d*–*f*, it preferentially detected the 5.0- and 9-kb mRNAs in these cell lines. This suggests that the difference between the 4.4- and the 5.0-kb mRNAs resides at the 3′ end of the gene and that the neuc(t)34 cDNA is derived from the 5.0-kb mRNA.

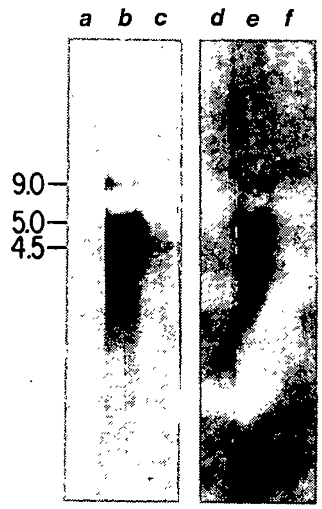

Fig. 1 Northern blot analysis of *neu*-related RNAs. Poly(A)$^+$ RNA (10 μg per lane) was hybridized with radiolabelled DNA from a genomic rat *neu* clone (*a–c*) or from the extreme 3′ end of the cDNA clone neuc(t)34 (*d–f*). RNA was extracted from Ki-*ras*-transformed NIH 3T3 cell line A5-2 (*a*, *d*), *neu*-transformed NIH 3T3 cell line B104-1-1 (*b*, *e*), or the Rat-1 fibroblast line (*c*, *f*) by standard methods[7], followed by oligo(dT) selection and separated on a formaldehyde-containing 1% agarose gel. *Hin*dIII-cleaved λ DNA was run as a marker. The RNA was transferred to nitrocellulose and hybridized in 50% formamide, $5\times$SSCPE, $1\times$ Denhardt's, 100 μg ml^{-1} boiled DNA and 10% dextran sulphate containing 5×10^6 c.p.m. of either a 500-bp *Bgl*I–*Stu*I fragment of genomic clone R4E (described in the text) or a 1.5-kb *Bam*HI fragment of neuc(t)34 nick-translated to a specific activity of 10^9 c.p.m. μg^{-1}; the nitrocellulose filters were washed at 65 °C in $2\times$SSCPE, 0.1% SDS and exposed to Kodak X-omat R film for 3 days at −70 °C using an intensifying screen.

The 4.8-kb insert of neuc(t)34 was introduced into the expression vector pSV2 (ref. 6) and tested for biological activity by transfection into NIH 3T3 cells. This clone was highly active in causing focus formation, yielding ~1,000 foci per μg of transfected DNA. Cell lines isolated from such foci contain a protein that is immunologically related to and co-migrates with the authentic p185 of B104-1-1 cells (data not shown). We conclude that neuc(t)34 is a biologically active clone of the *neu* gene present in B104-1-1 cells and encodes a full-length (or nearly full-length) p185 gene product.

Both strands of the coding region of neuc(t)34 were sequenced. Most parts of the gene were sequenced at least once each by the dideoxy and Maxam–Gilbert methods[7–9]. Figure 2 shows the DNA sequence of the *neu* cDNA and the predicted amino-acid sequence of its protein product; this predicted protein sequence is compared with that of the human EGF receptor in Fig. 3.

Neuc(t)34 has an open reading frame of 3,780 nucleotides and encodes a putative primary translation product of 1,260 amino acids that has a total M_r of 139,221, significantly smaller than the observed size of the *neu* gene product (M_r = 185,000). Glycosylation accounts for 15,000 daltons of the discrepancy (D. Stern and R.A.W., in preparation), and other post-translational modifications have not been excluded.

Sixteen of the 19 amino acids following the first ATG in the sequence are hydrophobic residues, consistent with the formation of a signal sequence for insertion into the membrane[10]. Residues 658–680 of the sequence are also highly hydrophobic, which suggests that this region represents a transmembrane domain. The location of these sequences and their similarity to sequences in the evolutionarily related EGF receptor[11] lead us to propose that p185 is organized similarly to the EGF receptor. Thus, the first few amino-acid residues of p185 would represent a cleaved signal sequence, the next 640 residues would include

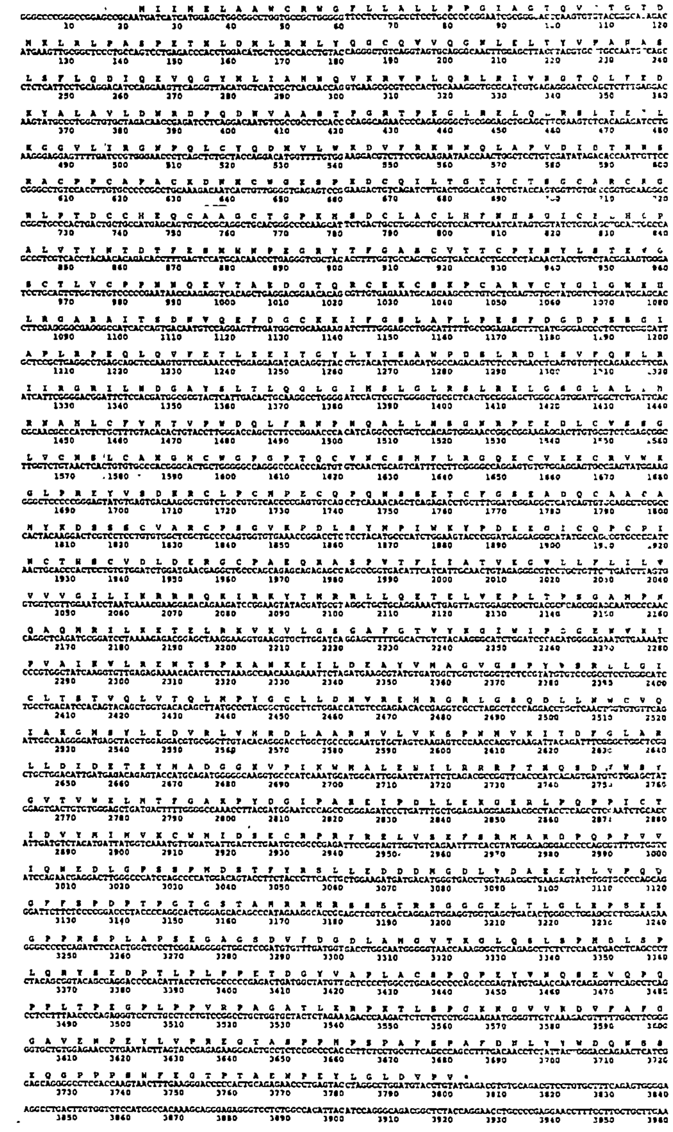

Fig. 2 DNA sequence of *neu*. Maxam–Gilbert sequencing[9] and M13 chain-termination sequencing[10,11] have been described elsewhere. Nucleotides 1–5 were generated by the tailing of the cDNA and do not represent sequences present in the RNA.

Methods. Poly(A)$^+$ RNA (5 μg) isolated as described in Fig. 1 legend was denatured in 12.5 mM methyl mercury hydroxide and reverse-transcribed in 50 mM Tris-HCl *p*H 8.3, 100 mM KCl, 10 mM $MgCl_2$, 5 mM dithiothreitol (DTT) and 0.5 mM of each dNTP with 50 μg ml^{-1} oligo(dT) (Collaborative Research), 120 U RNase (Promega Biotech) and 150 U reverse transcriptase (Boehringer-Mannheim) for 90 min at 42 °C. Nucleic acids were precipitated and the second-strand polymerization carried out in 50 mM KCl, 10 mM $MgCl_2$, 50 mM Tris *p*H 7.5, 1 mM DTT and 0.5 mM of each dNTP with 50 U DNA polymerase I large fragment (New England Biolabs) for 12 h at 16 °C after a second methyl mercury hydroxide denaturation. Hairpin loops were nicked with S_1 nuclease (600 U; Sigma) in 50 mM NaOAc *p*H 4.5, 0.2 M NaCl and 2 mM $ZnSO_4$ for 20 min at 37 °C. Double-stranded cDNA was size-selected over a BioGel A15 column (BioRad) and tailed using 30 U terminal transferase (BRL) in 200 mM potassium cacodylate, 2 mM DTT, 0.5 mM $CoCl_2$, 20 mM Tris *p*H 6.9, 600 μg ml^{-1} bovine serum albumin, and 0.1 mM dCTP for 2 min at 30 °C, phenol-extracted, ethanol-precipitated and annealed into dG-tailed *Pst*-cut pBR322 (BRL). 50,000 independent colonies were derived after transformation of cDNA into competent *Escherichia coli* and plating onto tetracycline-containing plates; these colonies were screened with a nick-translated fragment of a genomic clone of rat *neu* consisting of a 500-bp *Bgl*I to *Stu*I fragment which encompasses two exons of the *neu* tyrosine kinase domain. Nine recombinant plasmids reactive with this probe were purified; neuc(t)34, the largest, was sequenced.

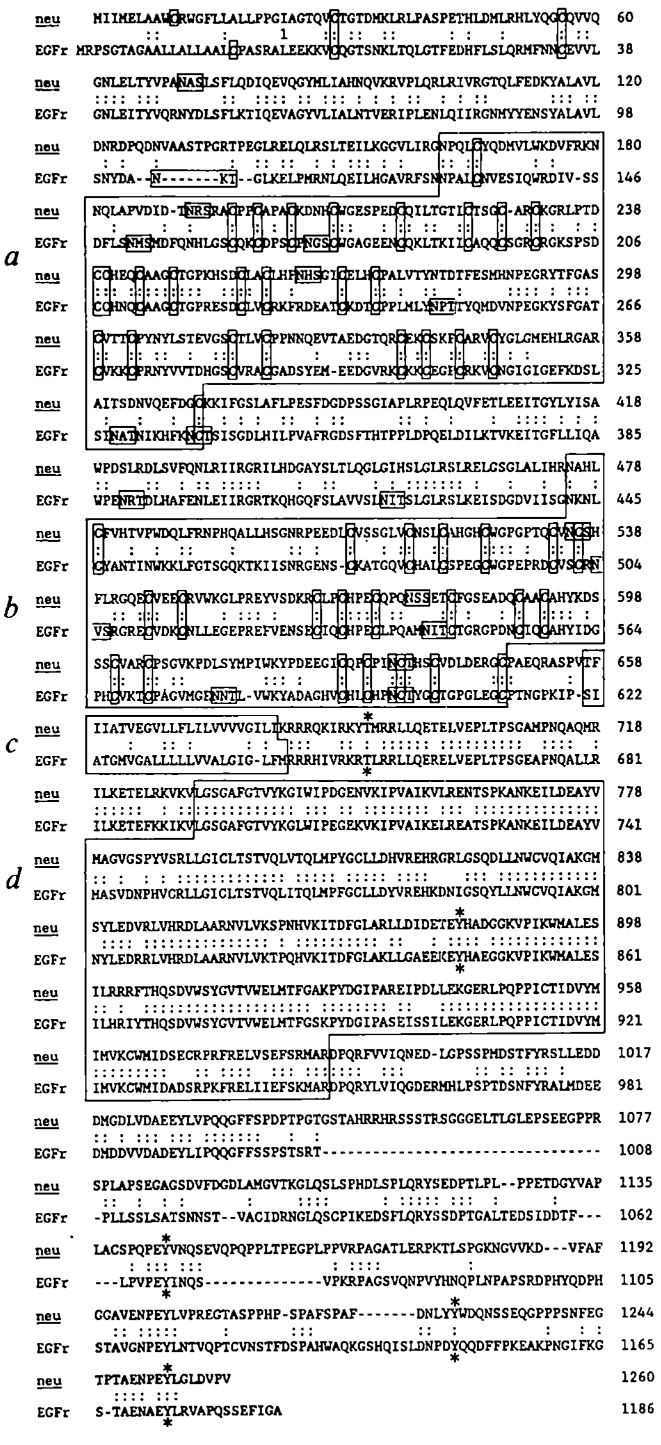

Fig. 3 Comparison of predicted amino-acid sequences of the *neu* gene product and the EGF receptor. Identities in sequence are marked by two dots between the conserved residues. All cysteine residues in the extracellular regions are boxed. Consensus sequences for *N*-linked glycosylation are marked by horizontal boxes. Asterisks denote residues which may be modified by phosphorylation. Boxed areas *a* and *b* represent the cysteine-rich domains of the extracellular part of the protein. *c*, Putative transmembrane domain; *d*, region homologous with the conserved region of the tyrosine kinase gene family. The first amino acid (leucine) of the mature EGF receptor protein is numbered (1).

an extracellular ligand-binding domain, and the 580 amino acids lying after the second hydrophobic (presumably transmembrane) domain would constitute cytoplasmic effector determinants of p185.

The putative extracellular domain of p185 contains two cysteine-rich areas between amino acids 162–372 and 475–649; these stretches contain 26 and 22 cysteines, respectively. This organization is strikingly similar to that of the comparable region of the EGF receptor[11]. As shown in Fig. 3, the two proteins show 43% identity of amino-acid residues in the extracellular portions. Note, however, that the positions of cysteines are highly conserved. All 50 cysteines predicted in the two extracellular domains are in equivalent positions in the two proteins.

These cysteine residues are also 80–90% conserved between these proteins and the insulin receptor[12,13]. As the peptide ligands of the insulin receptor and the EGF receptor are clearly unrelated, and as p185 does not bind either of these ligands (D. Stern and R.A.W., unpublished data), it seems that these residues must play a part other than forming the specific ligand-binding domain. They may constitute the structural scaffolding of the receptor or act to facilitate signal transduction after the receptor recognizes its ligand.

The two cysteine-rich regions of the EGF receptor bear homology with one another[11]. Similarly, the two cysteine-rich areas of *neu* are homologous. Comparison of the two EGF receptor domains, the two *neu* domains and the insulin receptor domain reveals that 15 residues out of ~180 appear to be conserved in this family of receptors (Fig. 4*a*). These residues include 11 cysteines as well as several other invariant residues. There are six predicted *N*-linked glycosylation sites in *neu*. Only one corresponds precisely in position to a glycosylation site in the EGF receptor.

A stretch of 25 hydrophobic amino acids followed by a lysine and three arginines appears to separate the extracellular from the cytoplasmic determinants of *neu*. The most obvious characteristic of the cytoplasmic region is the stretch of 250 amino acids homologous with the conserved region present in all tyrosine kinases[14]. Previous evidence indicated that the p185 protein has such an associated enzyme activity (D. Stern and R.A.W., in preparation); the sequence strongly suggests that this activity is intrinsic to the p185 protein itself.

Figure 4*b* compares this kinase domain with that of several other known tyrosine kinases and the cyclic AMP-dependent protein kinase. *neu* is more closely related to the EGF receptor gene than to all other members of this gene family; 82% of the amino-acid residues in this region of the EGF receptor and p185 are identical. The *neu* gene encodes the residues conserved among the proteins specified by the tyrosine kinase gene family (25% of the total residues in this domain), including the tyrosine residue that acts as an autophosphorylation site in pp60^{src} (residue 882 in the *neu* protein product).

After the kinase domain there are 60 amino acids that are 55% identical between the EGF receptor and *neu*. These residues are followed by a stretch of 198 amino acids in *neu* that are only distantly related to the last 172 amino acids of the EGF receptor; even when many gaps are inserted, only 58 residues (~30%) are comparable. This region of the protein consists of 20% proline residues and 10% each of glycine and serine residues, with only 25% of the residues being hydrophobic. Such hydrophilicity is characteristic of comparable regions of the EGF and insulin receptors.

Three tyrosine residues have been identified in the EGF receptor that serve as acceptor sites for *in vitro* autophosphorylation; these three and a fourth, as yet unlocalized, tyrosine are present in EGF receptor labelled *in vivo*[15]. The major site of phosphorylation of the EGF receptor *in vivo* is Tyr 1,173, 14 residues from the carboxy terminus of the EGF receptor. A similar tyrosine seems to exist eight residues from the carboxy terminus of p185 (Tyr 1,253). Tyrosine residues in homologous positions with the other two EGF receptor phosphotyrosine sites

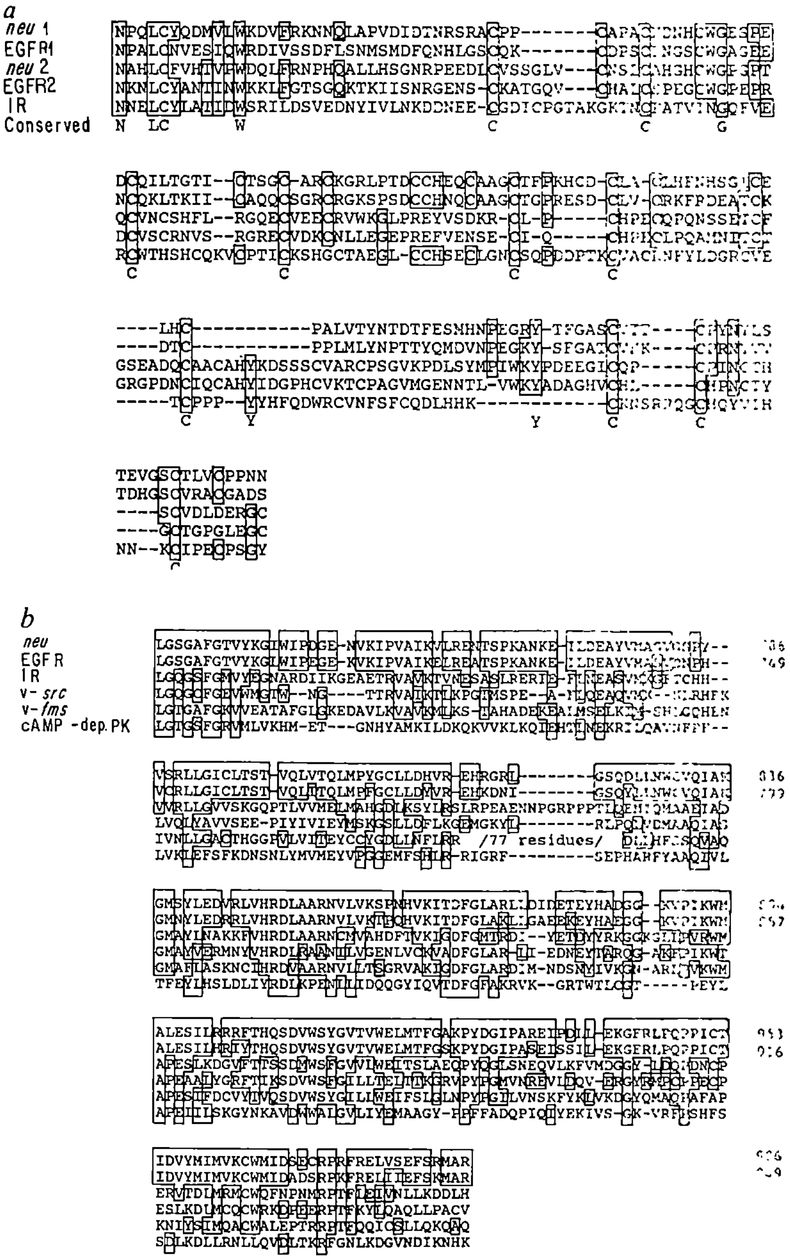

Fig. 4 *a*, Comparison of the cysteine-rich external domains of *neu*, the EGF receptor (EGFR) and the insulin receptor (IR). EGFR1 and *neu*1 are the more amino-terminal of the cysteine-rich domains found in these two proteins; *neu*2 and EGFR2 are the more carboxy-terminal of the domains found in the respective proteins. The following amino acids of the predicted protein sequences make up the domains shown: *neu*1, residues 162–323; *neu*2, 475–647; EGFR1, 129–291; EGFR2, 442–612, and IR, 122–292. Residues conserved in three or more of the five domains are boxed; residues present in all five are denoted underneath the sequences. *b*, Comparison of the putative tyrosine kinase domain of the *neu* gene product with the corresponding domains of the EGF receptor, the insulin receptor (IR), the products of the v-*src* and v-*fms* genes and the bovine cyclic AMP-dependent protein kinase. All residues shared between *neu* and one or more of the other kinases are boxed. The residues shown consist of amino acids 731–986 in the *neu* protein.

can also be found in *neu*. The tyrosine residues at EGF receptor position 1,068 and *neu* 1,144 are surrounded by similar residues in both proteins. The third tyrosine (EGF receptor, position 1,148) lies in a position homologous with a tyrosine residue in p185 (residue 1,227), but the residues surrounding it are not as similar.

Some or all of these tyrosines may act as regulatory sites for the *neu* gene product, but there are no data suggesting that they are phosphorylated. Another regulatory site may exist close to the membrane at position 691, 12 amino acids carboxy-terminal to the transmembrane domain. Exactly 12 amino acids from the transmembrane domain in the EGF receptor lies a threonine site that is phosphorylated by protein kinase C in response to the tumour promoter tetradecanoyl phorbol 13-acetate[16]. Phosphorylation at this site seems to cause the disappearance of a high-affinity class of EGF receptors from the cell surface[17,18]. The identically situated threonine in p185 could serve as such a site for negative regulation of receptor activity. Like Thr 654 of the EGF receptor and other known protein kinase C acceptor sites, it is surrounded by several basic residues[16].

Several oncogenes are mutated versions of cellular growth factors or their receptors[19], including v-*sis* (platelet-derived growth factor[20,21]), v-*erb-B* (truncated EGF receptor[22]), v-*fms* (slightly altered colony-stimulating factor (CSF)-1 receptor[23])) and v-*ros* (insulin receptor-related[12,13,24]). Various features of the deduced amino-acid sequence of p185 suggest that it is also a growth factor receptor, although the nature of its ligand is not yet known. Most suggestive is the colinearity and homology between *neu* and the gene for the EGF receptor. The extracellular cysteine-rich domains present in *neu* are characteristic of the EGF receptor, the insulin receptor and the low-density lipoprotein receptor[25]. An intracellular tyrosine kinase domain is also present on several growth factor receptors.

The accompanying report by Yamamoto *et al.*[26] describes the human homologue of the *neu* gene, which was isolated by virtue of its hybridization with the *erb-B* gene. Comparison of the human and rat sequences presented here reveals strong similarity between the two and demonstrates that they are in fact the same gene.

We thank Snezna Rogelj for assistance and advice on cDNA cloning techniques and Alan Schechter and David Stern for discussion and critical reading of the manuscript. We also thank T. Yamamoto for communicating his sequence before publication. This work was supported by Program Project Grant CA

17537-10 from the NCI and by a grant from the American Business Cancer Research Foundation. M.-C.H. was supported by a postdoctoral fellowship from the Cancer Research Institute. R.A.W. is an American Cancer Society Research Professor.

A novel v-*erb-B*-related gene, c-*erb-B*-2, which has been identified in the human genome[1,2], maps to human chromosome 17 at q21 (ref. 40), and seems to encode a polypeptide with a kinase domain that is highly homologous with, but distinct from, that of the epidermal growth factor (EGF) receptor[1]. The c-*erb-B*-2 gene is conserved in vertebrates and it has been suggested[1] that the *neu* gene, detected in a series of rat neuro/glioblastomas[3], is, in fact, the rat c-*erb-B*-2 gene. Amplification of the c-*erb-B*-2 gene in a salivary adenocarcinoma and a gastric cancer cell line MKN-7 suggests that its over-expression is sometimes involved in the neoplastic process. To determine the nature of the c-*erb-B*-2 protein, we have now molecularly cloned complementary DNA for c-*erb-B*-2 messenger RNA prepared from MKN-7 cells. Its sequence shows that the c-*erb-B*-2 gene encodes a possible receptor protein and allows an analysis of the similarity of the protein to the EGF receptor and the *neu* product. As a consequence of chromosomal aberration in MKN-7 cells, a 4.6-kilobase (kb) normal transcript and a truncated 2.3-kb transcript of c-*erb-B*-2 are synthesized at elevated levels. The latter transcript presumably encodes only the extracellular domain of the putative receptor.

Poly(A)$^+$ RNA was prepared from MKN-7 cells, a gastric cancer cell line in which the c-*erb-B*-2 gene is amplified[40] and over-expressed (see below). A cDNA library constructed from the MKN-7 mRNA was screened initially with a 440-base pair (bp) KX DNA fragment prepared from a c-*erb-B*-2 genomic clone and then with cDNA probes as described in Fig. 1 legend. Among 113 positive clones, pCER204 carried the longest insert of 4.0 kb, whereas the c-*erb-B*-2 mRNA is 4.6 kb long. Restriction mapping of the positive clones having an insert of >1.5 kb led to the identification of two distinct classes of clones (Fig. 1*A*),

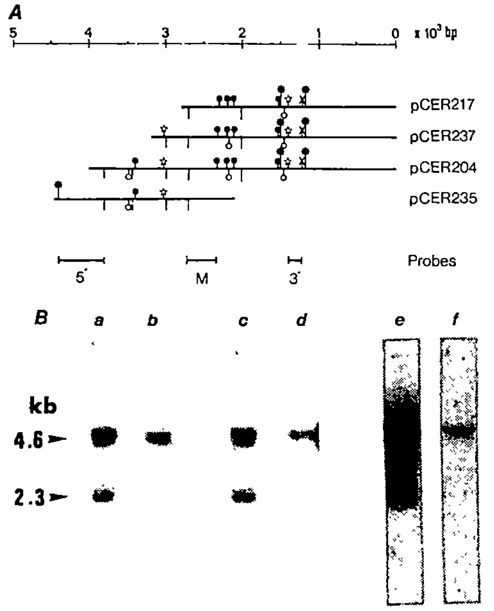

Fig. 1 Analysis of c-*erb-B*-2 clones. *A*, Restriction maps of c-*erb-B*-2 clones; *B*, Northern analysis of MKN-7 and placental mRNAs. *A*, Maps were constructed by the standard procedure for restriction digestion analysis of plasmid DNA[41]. Single or double digestion with restriction endonucleases *Kpn*I(×), *Eco*RI(☆), *Bam*HI (●), *Pvu*II (|), *Sma*I (*) and *Acc*I (○) was performed. The *Acc*I site at position 2.2 kb in this map is absent from the pCER217 insert but pCER237 and pCER204 were cleaved with the enzyme at this position. Sequence data reveal that pCER217 carries a deletion of 42 bp in this region (see Fig. 2 legend). The exon sequence of the 440-bp KX DNA prepared from the genomic clone λ107 (ref. 1) corresponds to a 150-bp *Eco*RI–*Kpn*I fragment of pCER217 (3' probe). A 450-bp *Pvu*II–*Bam*HI fragment of pCER217 (middle probe) and a 650-bp *Sma*I–*Pvu*II fragment of pCER235 (5' probe) were used for the second and third screenings, respectively, of the MKN-7 cDNA library. Total RNA was prepared from MKN-7 cells by the guanidine isothiocyanate–caesium chloride method[28]. Poly(A)$^+$ RNA was selected by two cycles of oligo(dT)–cellulose column chromatography[29]. A cDNA library was constructed by the method of Okayama and Berg[30], using 5.4 μg poly(A)$^-$RNA and 2.8 μg vector-primer DNA. (Avian myeloblastosis virus reverse transcriptase was from Dr J. W. Beard.) *Escherichia coli* MC1061 (ref. 31) was used for transformation[32]. Ampicillin-resistant transformants (60,000 independent clones) were first screened by hybridization at 60 °C for 16 h in the solution described previously[33] with the 440-bp KX DNA fragment. Among 21 distinctive positive clones, pCER217 carried the longest insert of 2.8 kb. To obtain clones harbouring cDNA for further upstream sequence, 50,000 independent clones of the same library were screened with the 450-bp *Pvu*II–*Bam*HI fragment mapped in the 5' portion of the pCER217 insert. Of 44 positive clones, plasmid pCER237 carried the longest insert (3.2 kb). A plasmid pCER235 was assumed to be derived from an aberrant c-*erb-B*-2 mRNA which shared 5' sequence with normal 4.6-kb mRNA, as described in the text. The MKN-7 cDNA library (100,000 clones) was again screened with a 650-bp *Sma*I–*Pvu*II restriction fragment derived from pCER235; 48 positive clones were obtained, one of which, designated pCER204, contained the longest insert (4.0 kb) and the restriction maps of its 5' one-third and 3' two-thirds were identical to those of pCER235 and pCER217, respectively. *B*, Nitrocellulose filters containing poly(A)$^+$ RNAs from MKN-7 (lanes *a*, *c*, *e*) and human placenta (lanes *b*, *d*, *f*) were hybridized with the 5' (lanes *a*, *b*), middle (lanes *c*, *d*) and 3' probes (lanes *e*, *f*) shown in *A*. Lanes *b* and *d* are photographs obtained after longer exposure of the film (overnight exposure for lanes *a*, *c*; 2 weeks exposure for lanes *b*, *d*). Poly(A)$^+$ RNA (2 μg) from MKN-7 cells was denatured with 50% formamide and 2.2 M formaldehyde and applied to a 1% agarose gel containing 2.2 M formaldehyde[34]. RNAs on the gel were transferred to a nitrocellulose filter[35], which was then hybridized for 16 h under stringent conditions (50% formamide, 4×SSC, 42 °C) with the DNA probes. After hybridization, the filter was washed under stringent conditions as described elsewhere[1]. Under the hybridization conditions used, no hybridization of the DNA probes with the EGF receptor mRNA was observed. The DNA probes were labelled with [α-^{32}P]dCTP (3,000 Ci mmol^{-1}; Amersham) by nick-translation[36].

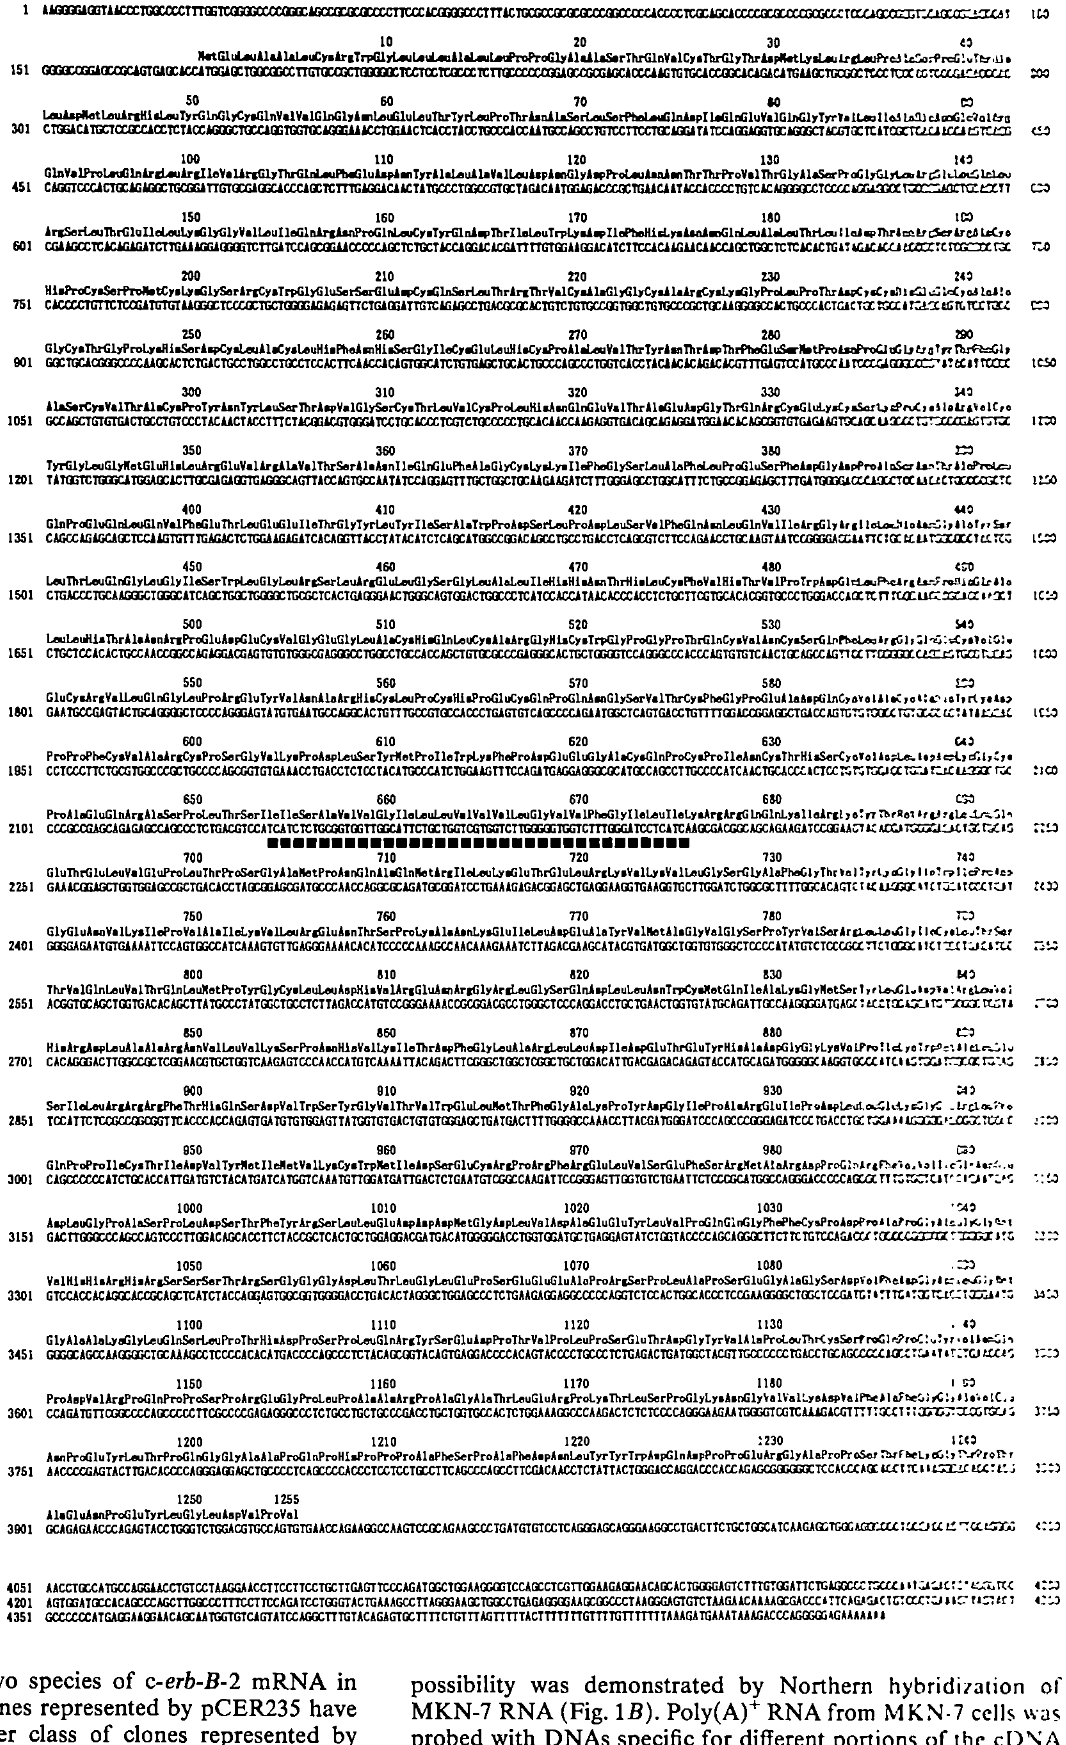

Fig. 2 The c-*erb-B*-2 cDNA nucleotide sequence and predicted amino-acid sequence. Nucleotides are numbered at both sides. Amino-acid sequence is numbered from the putative signal peptide above the sequence. Black dotted bars indicate the putative transmembrane region. The AATAAA box is followed (14 bp downstream) by the polyadenylated 3′ end of the mRNA. The nucleotide sequence from residues 1 to 1,810 was from pCER235 and that from residues 1,583 to the extreme 3′ end was from pCER217, except that the sequence of the 77-bp *Bam*HI fragment (2,314–2,390) was from pCER237, as a sequence of 42 bp was apparently deleted in pCER217 (see Fig. 1 legend). The overlapping nucleotide sequences (1,583–1,810) of pCER217 and pCER235 match. The extreme 3′ sequence of pCER235, which was derived from a sequence of unknown origin caused by chromosomal translocation is not shown here. The nucleotide sequence was determined by the Maxam-Gilbert[37] procedure and the dideoxy chain termination method in conjunction with bacteriophage M13mp19 (refs 38, 39).

suggesting that there are two species of c-*erb-B*-2 mRNA in MKN-7 cells. As cDNA clones represented by pCER235 have inserts of ≤2.3 kb, the other class of clones represented by pCER204 (or 217 and 237) was thought to be derived from the 4.6-kb mRNA. The pCER235 insert has a sequence that corresponds to the 5′ half, but not the 3′ half, of the pCER204 insert, suggesting that pCER235 was derived from mRNA which shares its sequence with the 5′ portion of normal 4.6-kb mRNA. This possibility was demonstrated by Northern hybridization of MKN-7 RNA (Fig. 1*B*). Poly(A)$^+$ RNA from MKN-7 cells was probed with DNAs specific for different portions of the cDNA clones. Using the 3′ probe, equivalent to the KX DNA probe[1], we observed a single species of 4.6-kb mRNA, which is expressed at an elevated level in MKN-7 cells (50-fold relative to placenta). However, both the *Pvu*II-*Bam*HI fragment (middle probe) and the *Sma*I-*Pvu*II fragment (5′ probe) reacted with a 2.3-kb

Homology with EGF receptor

Fig. 3 Amino-acid sequence of c-*erb-B*-2. ***A***, Alignment of the amino-acid sequences of c-*erb-B*-2 and EGF receptor (EGFR). Amino acids of the two proteins are numbered on the left. Identities in the sequences are marked by two dots between the two lines; predicted transmembrane regions are represented by dotted black bars; the possible *N*-linked glycosylation sites by wavy lines; horizontal lines indicate signal peptides (putative for c-*erb-B*-2); stars indicate cysteine residues in the sequence: solid stars are common to the two proteins and the open stars are specific to c-*erb-B*-2. The major sites of threonine and tyrosine phosphorylation of the EGF receptor or pp60^{src} are conserved in c-*erb-B*-2 and are shown by open and closed triangles, respectively. The amino-acid residues corresponding to the extreme carboxy terminus of pp60^{src} and v-*erb-B* protein are indicated by vertical arrows at positions 986 and 1,228, respectively. Boxed sequences show the cysteine clusters. ***B***, Schematic illustration of the c-*erb-B*-2 protein. Amino-acid sequence homologies of the c-*erb-B*-2 protein and the EGF receptor are shown. T, threonine and Y, tyrosine are possible phosphorylation sites. C, cysteine clusters (also boxed). —◇, Possible glycosylation sites. An open box at the amino terminus shows the putative signal peptide and that in the middle shows possible transmembrane sequence. The hydropathicity of the c-*erb-B*-2 sequence is also shown.

mRNA in addition to the 4.6-kb mRNA in MKN-7 cells, but with the 4.6-kb mRNA alone in placenta. The 2.3-kb mRNA was over-produced to about the same extent as the 4.6-kb mRNA.

Thus, the nucleotide sequences of the cloned inserts of pCER235 and pCER217 (237 or 204) were assumed to represent the overall sequence of the c-*erb-B*-2 gene product. The entire nucleotide sequence of 4,480 bp obtained from pCER235, pCER237 and pCER217 is shown in Fig. 2. The longest open reading frame is composed of 3,765 nucleotides, whose translated amino-acid sequence of 1,255 residues is also shown. The predicted initiation codon ATG is flanked by nucleotides that match Kozak's criteria[4] for a translation initiation site. A primary translation product of the c-*erb-B*-2 gene was calculated to have a relative molecular mass (M_r) of 137,895.

Previous analysis of the c-*erb-B*-2 genomic clone λ107 showed that the c-*erb-B*-2 gene product has a kinase domain that is highly homologous with that of EGF receptor/v-*erb-B*[1]. As shown in Fig. 3*A*, the entire amino-acid sequences of the two proteins are extremely similar and the hydrophilicity profiles[5] (Fig. 3*B*) and secondary structure[6] (data not shown) predicted from the amino-acid sequence of the c-*erb-B*-2 protein are also similar to those predicted for the EGF receptor. A sequence of 22 amino-acid residues (654–675) is strongly hydrophobic and

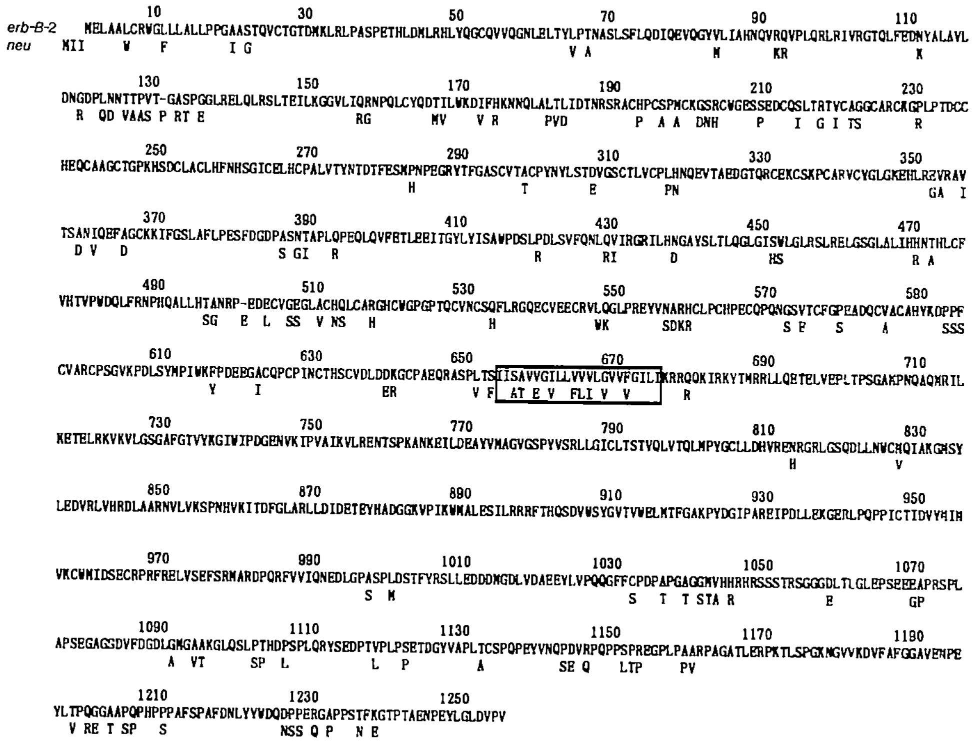

Fig. 4 Comparison of rat *neu* and human c-*erb-B*-2. The amino-acid sequence of c-*erb-B*-2 is compared with that of *neu* (kindly communicated by Dr R. A. Weinberg). Only non-identical amino acids are shown for *neu*. The amino acids for c-*erb-B*-2 are numbered above the sequence. The boxed sequence indicates the transmembrane domain.

could serve as a membrane-anchoring domain. This sequence, like those of other receptors[7-10], is followed immediately by basic amino acids (Lys-Arg-Arg), which helps in the correct allocation of the protein at the cell surface. The first 21 amino-acid residues are also highly hydrophobic, which suggests that they represent a signal sequence for membrane glycoprotein. Eight possible sites of *N*-linked glycosylation were identified in the amino-terminal moiety of the c-*erb-B*-2 protein. These data indicate that the two proteins with similar sizes have transmembrane topologies that resemble each other. Therefore, we tentatively conclude that the c-*erb-B*-2 protein is a receptor for an unknown growth factor.

The sequence of the putative extracellular domain shows 44% homology with the ligand binding domain of the EGF receptor. A striking similarity is the presence of two cysteine-rich regions, in which the spatial distribution of cysteine residues is virtually identical with that in the EGF receptor. The sequences of cysteine clusters are rather hydrophilic (Fig. 3*B*) and would facilitate the generation of a specific conformation for signal transmission through intramolecular or intermolecular S–S bridges, as is suggested for other receptors for growth factors[8-10]. These findings also suggest that the extracellular domains of the c-*erb-B*-2 protein and EGF receptor form similar configurations and bind to structurally related ligands. However, not only EGF but ligands such as tumour growth factor (TGF)-β, TGF-γ, fibroblast growth factor, erythropoietin, nerve growth factor, insulin and platelet-derived growth factor all failed to activate the kinase activity that is presumably intrinsic to the c-*erb-B*-2 protein (data not shown).

The sequence of 260 amino acids (residues 727–986), including the postulated ATP-binding site[11] of the cytoplasmic domain of the c-*erb-B*-2 protein, is homologous with the kinase domain of the EGF receptor (82% homology) and with retroviral oncogene products of the *src* family (25–40% homology[1]). Therefore, the c-*erb-B*-2 protein seems to have tyrosine kinase activity. Preliminary experiments using antiserum raised against a synthetic peptide of 14 amino-acid residues at the carboxy terminus of c-*erb-B*-2 show that the c-*erb-B*-2 protein gp185 exhibits tyrosine kinase activity (T.A. *et al.*, in preparation). The homology between the two proteins decreases to 32% in the 269 amino-acid residues at the carboxyl end. However, three major *in vitro* phosphorylation sites of the EGF receptor[12] are also conserved (tyrosine residues at 1,139, 1,222 and 1,248 of c-*erb-B*-2), indicating that the c-*erb-B*-2 protein could also be autophosphorylated.

Another interesting feature of the c-*erb-B*-2 protein is the presence of a threonine residue at position 686, surrounded by basic amino-acid residues, which is equivalent to threonine 654 of the EGF receptor on which protein kinase C-mediated phosphorylation occurs[13]. Therefore, the c-*erb-B*-2 protein may be phosphorylated by protein kinase C, which would play an important role in signal transmission as suggested for the EGF receptor.

Comparison of the nucleotide sequences and deduced amino-acid sequences of the recently characterized rat *neu* (see accompanying paper[14]) and human c-*erb-B*-2 (our present results) reveal that the *neu* gene is the rat counterpart of the c-*erb-B*-2 gene (see Fig. 4 for the amino-acid sequences). Surprisingly, only two amino acids in the kinase domain (residues 813 and 817) differ between the two proteins, although we do not know whether the c-*erb-B*-2 gene of MKN-7 cells can transform NIH 3T3 cells. The possible glycosylation sites of the *neu* product are located at positions corresponding to those of the c-*erb-B*-2 product, except that no sequence corresponding to Asn-Asn-Thr-Thr (positions 124–127 of c-*erb-B*-2) is found in *neu*, suggesting that the mature c-*erb-B*-2 protein is as large as the *neu* gene product gp185.

Evidence is accumulating that amplification and overexpression of a proto-oncogene can cause cell transformation *in vitro* and can play a part in the neoplastic process of human tumours[15-20]. Amplification and elevated expression of the EGF receptor gene have been observed in glioblastomas and in squamous carcinoma cell lines[21-24]. In contrast, amplification of the c-*erb-B*-2 gene has been seen in three human adenocarcinomas: one salivary adenocarcinoma[1], one mammary carcinoma[2] and one MKN-7 gastric cancer cell line, suggesting that increased expression of the c-*erb-B*-2 gene provides a selective advantage in the formation or the progress of tumours of epithelial cells.

Because the cDNA clone pCER235 derived from the 2.3-kb mRNA does not contain a signal for membrane anchoring of the predicted polypeptide (data not shown), the translation product of the 2.3-kb mRNA, corresponding to the sequence of the c-*erb-B*-2 ligand-binding domain, should be secreted by MKN-7 cells. Similarly, a truncated EGF receptor sequence has been reported to be over-expressed concomitantly with the EGF receptor in A431 cells[7,25,26], as a consequence of a strong aberration of the chromosomes[27]. Production of the truncated receptor in MKN-7 cells may also be caused by chromosomal aberration[40]. We cannot exclude the possibility that extracellular accumulation of truncated growth factor receptors is associated with the appearance of the transformed phenotype. It is also possible that they provide a growth advantage to the cells in culture, in which the growth factor receptors are over-expressed.

We thank N. Kitamura, H. Okubo and S. Nakanishi for help in constructing the MKN-7 cDNA library, H. Kawano for technical assistance and S. Sasaki for help in preparing the manuscript. We also thank Y. Kaziro for critical reading of the manuscript.

Molecular studies indicate that chimpanzee and gorilla are the closest relatives of man (refs 1–7 and refs therein). The small molecular distances found point to late ancestral separations[2,4,7], with the most recent being between chimpanzee and man, as judged by DNA hybridization[3,8]. Kluge[9] and Schwartz[10] contest these conclusions: morphological characters group a chimpanzee–gorilla clade with the Asian ape orang-utan in Kluge's cladistic study and with an orang-utan–human clade in Schwartz's study. Clearly, extensive sequencing of nuclear DNA is needed to resolve by cladistic analysis the branching order within Hominoidea[11]. Towards this goal, we are sequencing orthologues of the primate ψη-globin locus[12,13]. Here, we compare the newly completed sequences of orang-utan and rhesus monkey with human, chimpanzee, gorilla, owl monkey, lemur and goat orthologues. Our findings substantially increase the evidence indicative of a human–chimpanzee–gorilla clade with ancestral separations around 8 to 6 Myr ago. We also verify that neutral hominoid DNA evolved at markedly retarded rates.

The η locus is one of five ancient β-related globin genes linked in a cluster 5′-ε-γ-η-δ-β-3′ that arose from tandem duplications (200-100 Myr)[12,13]. This ancient η gene was embryonically expressed in early eutherians and persisted as a functional gene in artiodactyls, but became a pseudogene in proto-primates and was lost from rodents and lagomorphs. Previous work from this laboratory[13] established that the goat η gene sequence

Fig. 1 (Opposite) Aligned nuceotide sequences of seven primate ψη-globin genes and the active goat η-globin gene. Total DNA was isolated from orang-utan (*Pongo pygmaeus*) no. 1 liver (Yerkes Primate Center) and from a rhesus monkey (*Macaca mulatta*) blood sample (California Primate Center). DNAs were subjected to a series of limited *Eco*RI digestions and size-selected fragments, 15-25 kilobases (kb), were cloned into the λ vector Charon 32[33] by the procedure described by Slightom *et al.*[34]. Recombinant phage DNAs were packaged into phage capsids using the *in vitro* phage packaging procedure[35]. Charon 32 phage were plated on the recA⁻ *Escherichia coli* host ED8767[36] and screened using a ^{32}P-labelled 245-base-pair (bp) *Ava*II–*Eco*RI fragment isolated from the γ-globin cDNA clone pJW151[37]. The ψη-containing *Eco*RI fragments were subcloned into pBR322 (orang 7.0 kb, rhesus 10.0 kb). DNA sequencing was done using the chemical procedure described by Maxam and Gilbert[38]. The nucleotide sequences fo human, chimpanzee and gorilla are from Chang and Slightom[16], an owl monkey and lemur are from Harris *et al.*[12]. Only the 5′-flanking t exon 2 of the lemur sequence is orthologous to the η gene[12,15]; therefor only this part of the sequence is used in our analyses. The goat η-globi gene (goat ε^{II} gene) nucleotide sequence is from Shapiro *et al.*[14]. Th nucleotide sequencing numbering system is based on the overall alignment among these sequences. The complete nucleotide sequence for th human ψη-globin gene (HUMA) is presented on the top line an differences are given for the remaining sequences. Asterisks indicate th presence of gaps placed to minimize the number of geneic change during descent[13,39]. The simian ψη genes are divided into three exon separated by two introns each obeying the GT–AG splicing rule[40]. Lemu ψη[12,15] extends only to the 3′ end of exon 2 and has a defective intro 1 splice site. Intron 1 sequences are all 121 bp in length, while intron lengths vary between 841 to 877 bp. The 5′-flanking region of the oran ψη gene contains a 38-bp direct repeat (positions 205–244 and 245–282 common to hominoid ψη genes. Each repeat contains a CCAAT typ promoter element. The RNA polymerase II binding site (TATAA) ha diverged in the ψη genes from that found in normal β-type globi genes[41] (note positions 299–304). As in the other primate ψη genes th initiation codon (INT positions 384–386) of orang and rhesus sho defects that prohibit translation. All of the primate ψη genes share terminator sequence TGA (positions 1,885–1,888) and have the canon cal poly(A) addition signal[42]. With regard to the direct repeat at position 1,895–1,914 and 1,915–1,940, the 22-base gap (positions 1,895–1,914 in orang and rhesus could be the result of either two independen deletions or a deletion of the 5′ direct repeat in the stem catarrhine followed by a reduplication in the stem hominines. Exons terminate the ---→ sites.

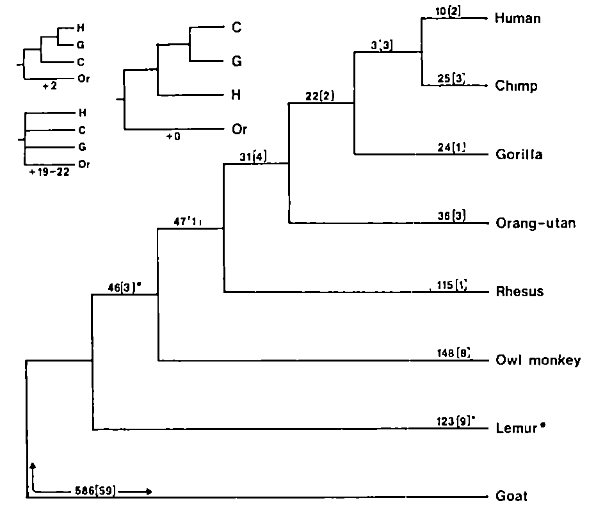

Fig. 2 Species relationship as indicated by a parsimony analysis[43,44] of the aligned sequences in Fig. 1. The upper right tree required 1,075 mutation events (1,218 after correction[31,32] for multiple substitutions occurring at the same site). Alternative trees (upper left) required 0, +2, +19-22 additional events. The 12 trees requiring +19-22 additional events resulted from breaking up a monophyletic African ape-human clade by introduction of orang. Branch lengths include both the corrected number of substitutions and the number of insertion/deletion events (the number of insertion/deletion events alone are given in brackets). The asterisk indicates the branches and corresponding link lengths in which geneic events were recorded only over those alignment positions that the much shorter lemur $\psi\eta$ sequence shared with other sequences. Normalization of the starred values requires multiplication by approximately 2.6. Ancestral sequences for the nodes of the upper right tree were deduced by our maximum parisomony method; from 548 ancestral-to-descendant substitutions occurring within the primate $\psi\eta$ gene region, the calculated[45] relative frequencies of the 12 types of substitutions were 20.5% G→A, 20.3% C→T, 14.3% A→G, 12.3% T→C, 5.9% G→C, 5.7% G→T, 4.7% C→A, 4.0% T→G, 3.3% A→T, 3.1% C→G, 2.8% T→A. The expected base composition at equilibrium (19% G, 29% A, 31% T and 21% C), calculated[46,47] from the above relative frequencies, was found to approximate to that of the large introns of β-globin-related genes (21% G, 29% A, 33% T and 17% C, averaged over 33 such introns) which are thought to represent selectively neutral DNA. Within the primate $\psi\eta$ gene regions the distribution of relative frequencies of substitutions was not found to differ significantly between exon and non-exon regions, nor did the exon and non-exon regions differ in overall substitution rates. Compared with the base composition of the exons of goat η and other functional globin genes (28% G, 22% A, 23% T and 27% C, averaged over 72 globin genes), the base composition of primate $\psi\eta$ exons (26% G, 26% A, 25% T and 23% C) is clearly evolving towards the equilibrium composition of neutral DNA.

(originally named ε^{11})[14] and primate η pseudogene sequences (each originally named either $\psi\beta^{15,16}$ or $\psi\beta1^{12,17}$) are orthologues. With addition of rhesus and orang orthologues (shown in Fig. 1 aligned against other η sequences), the seven primate pseudogenes represent most major taxonomic groups within primates. The rhesus and orang sequences prove to be typical representatives of this $\psi\eta$ locus; they contain mutations which inactivate functional genes (defective initiation codon at position 384-386, a stop codon at position 429-431, and frameshift deletions at orang position 447 and rhesus positions 441, 447 and 1,803; Fig. 1). The defective A→G substitution in the initiation codon is shared by all primate sequences, thereby supporting the deduction that the η-globin locus became nonfunctional in proto-primates to the primate radiation (approximately 60 Myr).

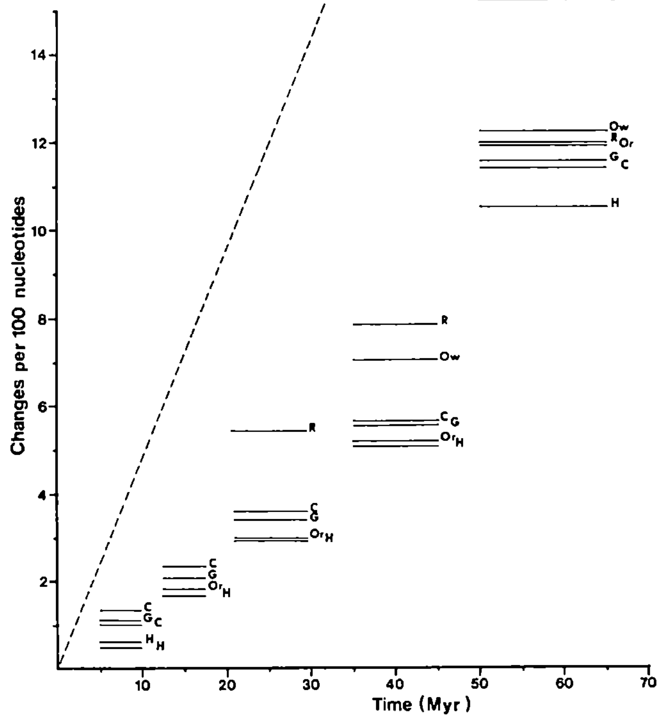

Fig. 3 The number of changes per 100 nucleotides from ancestral nodes to extant species plotted against a range of palaeontological time estimates[11,23-28]. The dashed line represents 5×10^{-9} substitutions per site per yr. 50-65 Myr is suggested as the divergence time of the prosimian and simian lineages, 35-45 Myr indicates Platyrrhini-Catarrhini divergence, 20-30 Myr indicates cercopithecoid-hominoid divergence, 13-18 Myr indicates *Pongo*-Hominine divergence and 5-10 Myr indicates human-chimpanzee-gorilla divergence plus human-chimpanzee (chimpanzee-gorilla) divergence times. The following labels for species are used: L, lemur; Ow, owl monkey; R, rhesus; Or, orang-utan; G, gorilla; C, chimpanzee; H, human. The slope of the dashed line represents the substitution values determined for mammalian pseudogenes other than the $\psi\eta$ genes and has been equated to the neutral mutation rate[18,19].

Trees describing the genealogical relationships of the η-globin sequences were constructed by the most parsimonious placement of nucleotide substitutions. This cladistic procedure does not require clock-like behaviour in rates of change but only that matches in nucleotide sequence among taxa result more often from shared common ancestry than from convergencies, reversals or parallelisms. The two most parsimonious trees found (Fig. 2) required 1,075 independent genetic events to explain the pattern of variation among the eight η-globin sequences. One of these two trees, after separation of *Gorilla*, places only three derived mutations on the common stem of a *Homo*(human)-*Pan*(chimpanzee) branch: a deletion at position 1,491-1,494, an insertion at position 1,739 and a deletion at position 1,916. The last event is equivocal because an alternative parsimony solution redistributes the duplication and deletion events that occur in that region (positions 1,895-1,941). In the other most parsimonious tree, *Homo* separates from the common stem of a *Pan-Gorilla* branch; this latter grouping is obtained by two transitional substitutions (G→A) at positions 2,213 and 2,238. No events uniquely support a human-gorilla branch. As evident from Fig. 2, a Homininae branch of *Homo-Pan-Gorilla* is strongly supported; there are 22 derived mutations on its common stem: an insertion at positions 1,385-1,391, a deletion at position 1,879 and 20 nucleotide substitutions of which 17 are unequivocal (positions 121, 300, 326, 422, 631, 654, 750, 1,185, 1,214, 1,263, 1,307, 1,381, 1,467, 1,484, 1,592, 1,677, 1,840).

TMH indicates median sequence divergence determined from thermal stability measurements[8,29,30]. Dist. indicates divergence determined from nucleotide sequences. TMH-C or Dist.-C indicates divergence after correction for multiple substitutions[31,32]. For taxonomic comparisons the following abbreviations are used: Huma., human; Chim., chimpanzee; Oran., orang-utan; Homi., homininae; Cerc. Cercopithecoidea; Cebo., Cebroidea; Pros., lemurs (or galago); Euth., goat (or tree shrew). Note that comparisons involving the goat η sequence are underestimates due to the inclusion of conserved functional exon regions in these comparisons. This is particularly true in the lemur-goat η comparison in which the shortened lemur sequence corresponds to the most conserved region (exons 1 and 2) of the functional goat η gene.

*Values from ref. 8.

†Values from ref. 29.

‡Values from ref. 30.

§Divergence from tree shrew rather than goat.

¶Divergence from galago rather than lemur.

The genealogical family Hominidae (Homininae plus *Pongo*) is also very strongly supported; it is defined by three deletions (at positions 164, 966-970, 1,610-1,637), an insertion (positions 245-282) and 27 separate substitutions of which 24 are unequivocal (positions 5, 66, 383, 405, 495, 573, 780, 853, 926, 1,268, 1,278, 1,334, 1,422, 1,667, 1,859, 1,949, 2,002, 2,093, 2,137, 2,138, 2,161, 2,188, 2,193, 2,213). A total of 47 shared derived mutations define infraorder Catarrhini and another 46 define suborder Anthropoidea.

Rates of $\psi\eta$ sequence evolution were calculated from the number of events on the branches of our genealogical reconstruction (Fig. 2). It is apparent from Fig. 3 that marked variations in lineage rates exist. The fastest rates are shown by lemur (2.7×10^{-9}) and in the early common simian stem (2.9×10^{-9}), intermediate rates by owl monkey and rhesus monkey and the slowest rates by hominoids (averaging 1.3×10^{-9} in descent from the catarrhine branchpoint). All primate rates are less than the average mammalian neutral rate[18,19] and the two slowest rates, those of human and orang lineages, are only one-fifth this average neutral rate.

It follows from the close correspondence of interspecies DNA divergence estimated by DNA hybridization and $\psi\eta$ sequence results (Table 1) that the retardation of primate rates evident in the $\psi\eta$ sequences applies to total single-copy DNA. This supports Britten's analysis[20], which demonstrated that rates of neutral DNA sequence evolution vary by as much as a factor of five, with hominoids and some bird taxa showing the slowest rates and rodents, *Drosophila* and sea urchins showing the fastest rates. Explanations for the retarded hominoid rate invoke lengthening generation times, improved DNA repair mechanisms and combinations of both factors[20-22].

Clearly varying rates of evolution in different lineages affect the ability of a global molecular clock to predict specific divergence times. An alternative approach is to focus on a more localized set of branchpoints within a particular lineage and to use one or more well-established palaeontological time points within that lineage to calibrate a local clock. We have carried out such local clock calculations for Catarrhini, Hominidae and Homininae using the Anthropoidea branchpoint as an outside reference on assigning a palaeontological time of 35-45 Myr[23,24] to this reference. The date found for the Catarrhini branchpoint is 22.2-28.2 Myr, the Hominidae (*Pongo*-Homininae) branchpoint is 12.7-16.4 Myr and the Homininae branchpoint is 6.3-8.1 Myr. These local clock dates correspond well with assessments of the hominoid fossil record[11,25-28]. However, applying the local clock calibration to simian-lemur, primate-nonprimate and *Mus-Rattus* DNA hybridization distances results in dates that are too ancient (72-92 Myr, 98-125 Myr and 52-68 Myr).

In conclusion, to a high degree of certainty, the DNA sequence data have established the genealogical validity of grouping *Homo*, *Pan* and *Gorilla* and excluding *Pongo* in a monophyletic subfamily Homininae. However, within Homininae the relationships remain unclear, perhaps due to relative close divergence points. Our analysis of the primate $\psi\eta$ globin genealogy also raises questions concerning the validity of using global clocks to estimate divergence times. Because of variability in rates of divergence in different lineages, we suggest that local clocks in some cases yield more accurate divergence times.

We thank Dr E. A. Zimmer for the gift of orang-utan No. 1 DNA, Dr S. Martin for rhesus DNA, J. Reneke and J. Bliska for help in isolating phage and Dr N. Maeda for communicating restriction enzyme map data of the rhesus β-globin gene cluster before publication. J.L.S. thanks Drs Frederick R. Blattner and Oliver Smithies for the use of shared laboratory space and equipment in the Department of Genetics, University of Wisconsin. We also thank Wen-Hsiung Li, Roy J. Britten and Raoul E. Benveniste for providing us with pre-publication manuscripts. This study was supported by grants from NIH, HD16595 (J.L.S.), NSF, BSR82-07336 (M.G.) and Alfred P. Sloan Foundation (M.G.).

fgr proto-oncogene mRNA induced in B lymphocytes by Epstein–Barr virus infection

Marc S. C. Cheah*, Timothy J. Ley†, Steven R. Tronick* & Keith C. Robbins*

* Laboratory of Cellular and Molecular Biology, National Cancer Institute and
†Clinical Hematology Branch, National Heart, Lung and Blood Institute, Bethesda, Maryland 20205, USA

Several acute transforming retroviruses encode tyrosine-specific protein kinases which possess structural and functional relationships to cell-surface receptors for certain growth factors[1,2]. One such tyrosine kinase is encoded by the *onc* gene, v-*fgr*, of Gardner–Rasheed feline sarcoma virus (GR-FeSV)[3–6]. Recently, we have isolated and characterized the human gene, c-*fgr*, corresponding to the viral *onc* sequence and have shown that c-*fgr* is a unique gene located on the short arm of chromosome 1 (ref. 7). Here we report that certain lymphomas (but not sarcomas or carcinomas) express *fgr*-related messenger RNA. This transcript is detected in Burkitt's lymphoma cell lines naturally infected with Epstein–Barr virus (EBV), but not in EBV-negative Burkitt's lymphoma cells. Normal umbilical cord or peripheral blood lymphocyte lines established *in vitro* by EBV infection also contain detectable c-*fgr* mRNA. Moreover, a 50-fold increase of the steady-state c-*fgr* mRNA concentration is observed when uninfected Burkitt's lymphoma cell lines are deliberately infected with EBV. These findings demonstrate for the first time the induction of a proto-oncogene in response to infection by a DNA tumour virus.

To investigate whether the *fgr* proto-oncogene was expressed in human tumour cells, RNAs were prepared from selected cell lines representing a diverse spectrum of human cancers. After selection on oligo(dT) columns, poly(A)$^+$ RNAs were examined for the presence of v-*fgr*-related mRNA by Northern blotting. c-*fgr* transcripts were detected in 6 of 11 cell lines derived from myelo- or lymphoproliferative disorders, but not in any of the 9 carcinoma or 6 sarcoma cell lines examined. In a representative experiment (Fig. 1) the *fgr*-related mRNA detected was 3 kilobases (kb) long, which is in close agreement with the length of the transcript detected in normal human lung tissue[7].

Because our initial survey had indicated the presence of the c-*fgr* transcript in cell lines derived from lymphoproliferative disorders, our analysis was extended to include various B-cell lines derived from African and American undifferentiated lymphomas of the Burkitt and non-Burkitt types. As summarized in Table 1, the c-*fgr* transcript was detected in approximately half of the lymphoma cell lines tested. All cell lines infected with EBV expressed detectable *fgr* mRNA. One non-Burkitt's

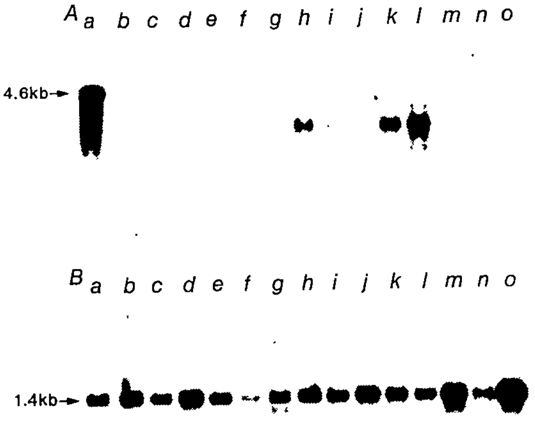

Fig. 1 *A*, Survey of human tumour cell lines for expression of c-*fgr*-related RNA. Poly(A)$^+$-containing RNA was prepared, as described elsewhere[22], from human tumour cell lines and examined by the Northern technique using a v-*fgr*-specific DNA fragment as probe[7]. Carcinoma-derived cell lines A2054, A549, A2182, A431, A1847 and A2199 (ref. 23 and S. A. Aaronson and N. Ellmore, unpublished) (lanes *b*–*g*, respectively), lymphoma-derived cell lines JI, MC116, JD38, Raji and Namalwa (lanes *h*–*l*, respectively), as well as sarcoma-derived cell lines A375, A1632 and A2984 (ref. 23 and S. A. Aaronson and N. Ellmore, unpublished) (lanes *m*–*o*, respectively), were examined. RNA from GR-FeSV-infected mink cells (lane *a*) was used as a control. The relative amounts of hybridizable RNA transferred to nitrocellulose filters were shown to be similar by rehybridization with a GR-FeSV-derived, actin-specific probe (*B*).

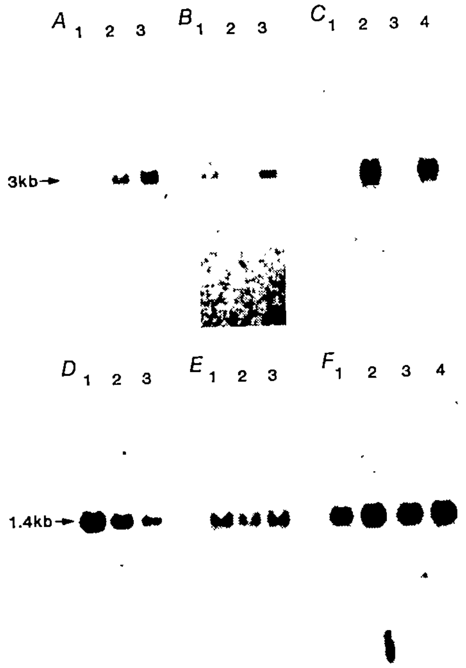

Fig. 2 Expression of *fgr*-related mRNA in cells infected with EBV *in vitro*. Poly(A)$^+$-containing RNAs prepared from EBV-infected normal peripheral (*A*) or umbilical cord (*B*) blood lymphocytes, as well as uninfected (*C*, lanes 1, 3) or EBV-infected (*C*, lanes 2, 4) BJAB (lanes 1, 2) or Ramos (lanes 3, 4) Burkitt's lymphoma cell lines[24,25], were analysed as described in Fig. 1 legend. Relative amounts of hybridizable RNA transferred to nitrocellulose filters were shown to be similar by rehybridization with a GR-FeSV-derived actin-specific probe (*D*–*F*).

lymphoma cell line that expressed detectable c-*fgr* mRNA was not nuclear antigen(EBNA)-positive. These results revealed an association of *fgr* proto-oncogene mRNA with Burkitt's lymphoma cells which had been naturally infected with EBV.

To further assess the association between expression of the *fgr* proto-oncogene and EBV infection, we examined RNAs prepared from normal umbilical cord or peripheral blood lymphocyte cell lines established as a result of EBV infection. Figure 2 shows that the *fgr* proto-oncogene transcript was expressed at detectable levels in each of these cell lines, providing further evidence that EBV infection was responsible for the increased concentration of *fgr* proto-oncogene transcripts detected in the lymphoid cells. Preliminary efforts to determine whether normal B lymphocytes express c-*fgr* mRNA have revealed that normal peripheral blood mononuclear cells contain this transcript. However, such preparations consist of a variety of cells, of which only about 10% are B lymphocytes. Thus, further studies will be required to identify the source of c-*fgr* mRNA in peripheral blood (see note added in proof). In any case, the fact that normal lymphocytes become immortalized as stable cell lines in response to EBV infection, but do not acquire fully neoplastic properties, suggests that expression of c-*fgr* RNA alone is not sufficient to induce the neoplastic state.

We extended our analysis to EBV-negative Burkitt's lymphoma cells which are susceptible to EBV infection. BJAB cells infected with a prototype EBV, B95-8, which is capable of immortalizing normal B lymphocytes[8,9], or Ramos cells infected with a nontransforming derivative, P3HR-1 (ref. 10), were examined for the presence of *fgr* proto-oncogene transcripts. These converted cell lines are known to closely resemble their parental lines in morphology and with regard to karyotype and HLA- and B-antigen typing[11]. As shown in Fig. 2*C*, uninfected BJAB or Ramos cell lines expressed little or no detectable c-*fgr* mRNA, whereas cells infected with either of the two EBV strains expressed the c-*fgr* transcript. We conclude from these results that the increase in c-*fgr* RNA concentration was a specific event associated with EBV infection. Moreover, as infection with either an immortalizing or a non-immortalizing EBV strain led to an increase in the steady-state concentration of *fgr* mRNA, we suggest that altered c-*fgr* expression alone is insufficient for lymphocyte immortalization.

To assess the level of c-*fgr* transcript induction in response to EBV infection, DNA fragments containing a dihydrofolate reductase exon (*dhfr*)[12] or human c-*fgr* sequences[7] were used as probes in quantitative S_1 nuclease protection experiments. As a positive control for each probe, RNA prepared from normal human peripheral blood mononuclear cells was examined (Fig. 3). As expected, a major band of 144 nucleotides was protected with the *dhfr* probe in the cell lines that were in cycle[12]. The c-*fgr* DNA probe detected sequences of 165 and 120 nucleotides, sizes which were consistent with those of v-*fgr*-related stretches present in the DNA fragment used as a probe (data not shown). The intensity of bands detected with each DNA probe increased as a function of RNA concentration, making it possible to quantitate the level of c-*fgr* mRNA induction. RNAs from uninfected or EBV-infected cell lines contained similar amounts of *dhfr* mRNA, as indicated by the intensity of the 144-nucleotide *dhfr* probe fragment (Fig. 3*B*). In contrast, c-*fgr* sequences of 165 and 120 nucleotides were protected by RNA from EBV-infected but not uninfected BJAB or Ramos cells. By varying the exposure times, we calculated that the steady-state concentration of c-*fgr* mRNA increased by at least 50-fold in response to EBV infection. Based on other data obtained with probes of similar specific activity[13], we estimate that the EBV-infected lines contain <20 copies of c-*fgr* mRNA per cell.

The correlation of increased *fgr* proto-oncogene expression with EBV infection of transformed lymphocytes was nearly absolute. Increased concentrations of c-*fgr* mRNA were detected in Burkitt's lymphoma cells whether infected naturally or deliberately in tissue culture. In addition, each of the umbilical cord or peripheral blood lymphocyte cell lines established by EBV infection expressed c-*fgr* mRNA. Increases in the levels of transcripts related to other mammalian tyrosine kinase-coding *onc* genes (v-*fms* and v-*fes*) were also detected in some EBV-infected Burkitt's lymphoma cell lines (data not shown), but these RNAs were not consistently detected in EBV-infected lines and were, in some cases, detectable in uninfected cell lines. Taken together, these results establish a specific relationship between EBV infection and expression of the *fgr* proto-oncogene, which suggests that EBV infection results in transcriptional activation of c-*fgr*. Further studies will be required to show whether increased transcription rates alone are responsible for the increase in steady-state concentration c-*fgr* mRNA.

Integration of EBV into host chromosomal DNA of Namalwa and IB4 cell lines has been described elsewhere[14]. In Namalwa cells, the site of integration is close to the *fgr* proto-oncogene locus on chromosome 1 (refs 7, 14), whereas in IB4 cells the

The characteristics of the cell lines examined have been described previously[19,20]. The concentration of 3-kb *fgr*-related mRNA was determined by analysing 10 μg of poly(A)$^+$ RNA in formamide-formaldehyde agarose gels as described[21]. The relative amounts of hybridizable RNA transferred to nitrocellulose filters were determined by rehybridization with a GR-FeSV-derived actin-specific probe.

* Detectable levels were graded by exposing hybridized nitrocellulose filters for various times as follows: +++, detected after overnight exposure; ++, detected after 2 days of exposure; +, detected after 5 days of exposure; −, not detectable after 5 days of exposure.

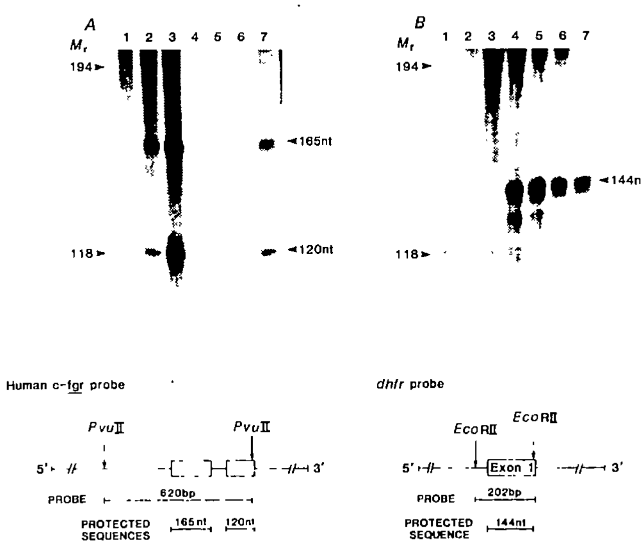

Fig. 3 Quantitation of *fgr* proto-oncogene mRNA induction in response to EBV infection. DNA fragments derived from the region 6.0-6.62 kb of the human *fgr* proto-oncogene[7] (*A*) or the 5′ end of the dihydrofolate reductase gene[12] (*B*), were cloned into M13 phage vectors and used as templates for the synthesis of uniformly labelled anti-sense DNA probes. Conditions for hybridization of total cellular RNA with the DNA probe, S_1 nuclease digestion and polyacrylamide gel electrophoretic analysis of protected sequences were as described elsewhere[26,27]. Samples tested included 5 μg (lanes 2) or 20 μg (lanes 3) total cellular RNA from normal human peripheral blood mononuclear cells, 20 μg RNA from uninfected Ramos (lanes 4) or BJAB (lanes 6) cells, as well as P3HR1-infected Ramos (lanes 5) or B95-8-infected BJAB (lanes 7) cell lines. Negative controls consisted of labelled probe hybridized in the absence of RNA and treated with S_1 nuclease (lanes 1). As expected, no *dhfr* mRNA was detected in peripheral blood mononuclear cells as these cells were not in cycle. The diagrams at the bottom of the figure show human c-*fgr* and *dhfr* exons and their protected sequences. The extent and locations of the human c-*fgr* exons shown were confirmed by nucleotide sequence analysis.

EBV genome integrates into chromosome 4. In the case of the Namalwa cell line, EBV may have a *cis*-acting effect on the expression of the *fgr* proto-oncogene. However, in most cases the influence of EBV on c-*fgr* is more likely to be *trans* as the EBV genome typically exists in the host as an episome. Thus, the isolation of EBV genes having specific functions may make it possible to identify the region of the EBV genome responsible for the increase in *fgr* proto-oncogene mRNA.

Several lines of evidence suggest that Burkitt's lymphoma results from a multi-step process involving the alteration of several genetic elements[15]. Epidemiological data suggest that EBV has an important role in the aetiology of African Burkitt's lymphoma[16]. Molecular studies have strongly implicated alterations of *myc* proto-oncogene expression in the process leading to American as well as African Burkitt's malignancies[17,18]. However, there is no evidence to indicate that such genetic alterations are the only changes required to achieve lymphoid cell transformation. From the results of the present study we conclude that increased concentrations of c-*fgr* mRNA alone are not sufficient to induce malignant transformation of normal lymphocytes or even to immortalize them as continuous cell lines. Moreover, we have no direct evidence that EBV-induced immortalization involves c-*fgr*. Nevertheless, our results are consistent with the possibility that one step in EBV-induced B-cell immortalization involves transcriptional activation of the *fgr* proto-oncogene in response to an EBV-encoded function.

We thank N. Ellmore, L. Mickley and C. Lengel for technical assistance; N. Raab-Traub, I. T. Magrath and D. Ablashi for providing cell lines; T. Kawakami for making unpublished nucleotide sequence data available to us; T. Shimada and A. Nienhuis for the *dhfr* probe; and S. Aaronson for helpful discussions.

Note added in proof: Recent experiments have revealed that c-*fgr* mRNA is not expressed in normal resting or activated B lymphocytes.

Cauliflower mosaic virus (CaMV) is a double-stranded DNA plant virus[1-3] for which evidence has been presented that its replicative cycle involves a reverse transcription step[4-14]. Until now, however, there has been no direct evidence for such a step. The sequence of the CaMV genome contains a number of open reading frames, one of which (ORF V) encodes a protein of predicted sequence homologous to retroviral reverse transcriptases[10]. We have cloned this gene, and expressed it in the yeast *Saccharomyces cerevisiae*. We report here that yeast expressing this gene accumulate significant levels of reverse transcriptase activity. This provides strong evidence that CaMV really does replicate through an RNA intermediate, converted to DNA by reverse transcriptase.

To obtain the direct expression of the ORF V gene in yeast cells, we constructed the plasmid pAM.ORFV in which the entire ORF V gene is inserted immediately downstream from the acid phosphatase (APase) promoter of the yeast expression vector pAM82 (ref. 15) (Fig. 1*b*). The resulting Leu^+ yeast transformant AH22/pAM.ORFV was obtained. The integrity of the ORF V gene in pAM.ORFV was confirmed by fine restriction mapping of a rescued pAM.ORFV from AH22/pAM.ORFV cells (Fig. 1*b*).

AH22/pAM.ORFV and AH22/pAM82 cells were grown in a liquid medium and then induced in phosphate-deprived medium. The extract from AH22/pAM.ORFV cells, but not

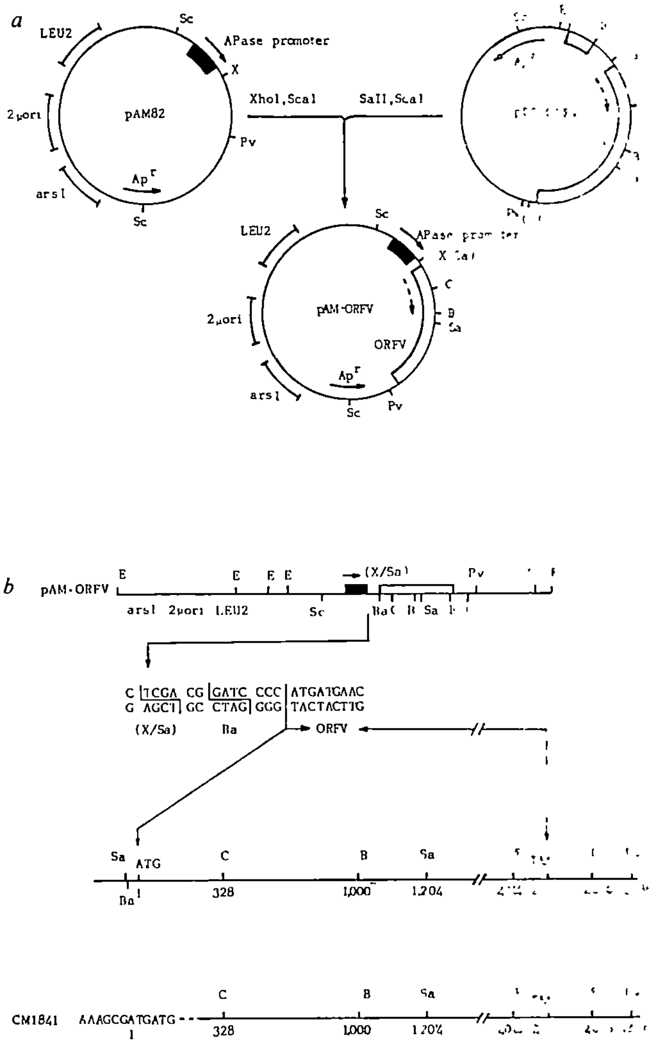

Fig. 1 *a*, Construction of yeast expression plasmid pAM.ORFV. Restriction sites for the enzymes *Bam*HI (Ba), *Bgl*II (B), *Cla*I (C), *Eco*RI (E), *Pvu*II (Pv), *Sal*I (Sa), *Sca*I (Sc) and *Xho*I (X) are indicated. The fusion junction of *Xho*I and *Sal*I sites is shown as (X/Sa). Solid boxes represent the APase promoter region; open boxes represent the ORF V sequence. An arrow above the APase promoter region shows the direction of transcription started from the APase promoter. A broken arrow shows the direction of translation started from the ATG initiator codon of the ORF V gene. Ap^r represents the ampicillin resistance gene. *b*, Fine restriction map of pAM.ORFV rescued from AH22/pAM.ORFV cells. All symbols represented are the same as indicated in *a*.

Methods. *a*, ORF V gene was recovered from pCaMV10 (ref. 29), which contains a full-length copy of CaMV strain CM1841 cloned at the *Sal*I site of pBR322. In the plasmid, the ORF V gene was contained in a form interrupted at the *Sal*I site by pBR322 sequences. The *Cla*I/*Sal*I fragment containing the 5′ half of ORF V and the *Pvu*II/*Sal*I fragment containing the whole 3′ half of ORF V were excised from pCaMV10, re-ligated at the *Sal*I site and cloned into the *Cla*I/*Pvu*II site of pBR322 (pBR.ORFV-D). The *Pst*I fragment containing the whole 5′ half of ORF V was excised from pCaMV10 and 'nibbled' with *Bal*31 to the nucleotide next to the first ATG in two adjacent putative initiation codons, followed by *Bgl*II digestion. This fragment and the *Eco*RI/*Bgl*II fragment, which contains the 3′ half of ORF V from pBR.ORFV-D, were inserted together into the *Sma*I/*Eco*RI site of M13mp8. pBR.ORFV, which contains the entire ORF V gene in correct orientation, was obtained by the insertion of the *Bgl*II fragment of the recombinant of mp8 and ORF V into the *Bgl*II site of pBR.ORFV-D. The *Sal*I/*Sca*I fragment of pBR.ORFV, containing the entire ORF V gene, was inserted into the *Xho*I/*Sca*I site of pAM82. The *Sal*I terminus of the former fragment was joined to the *Xho*I site of pAM82 at a position downstream from the APase promoter. The resultant plasmid, pAM.ORFV, was directly transformed into yeast AH22 cells. Transformation of yeast was performed by the modified method of Beggs[30] as described by Sherman *et al.*[31]. Leu$^+$ transformants were selected on high-P_i medium containing 2% agar. *b*, *E. coli* C600 (M^-, R^-) was transformed with the plasmid DNA fraction which was prepared from spheroplasted AH22/pAM.ORFV cells (2×10^7 cells). The rescued pAM.ORFV DNAs were prepared from eight clones out of the ampicillin-resistant transformants (1×10^3 per μg DNA) and subjected to fine restriction mapping.

from AH22/pAM82 cells, revealed an inducible RNA-dependent DNA polymerase activity which could use poly(rC)-oligo(dG) as well as poly(rA)-oligo(dT) as template-primer (Table 1). Eukaryotic DNA polymerases β and γ are known to use poly(rA)-oligo(dT), but not poly(rC)-oligo(dG)[16]. The low levels of activity observed with the extract from non-induced AH22/pAM82 cells could be explained by the presence of a β-type DNA polymerase observed previously in yeast[17]. The activity seen on poly(rC)-oligo(dG) with the extract from induced AH22/pAM.ORFV cells corresponds to the distinctive template specificity of a retroviral reverse transcriptase[18]. Negligible amounts of ^{3}H-dGMP were incorporated using poly(rA)-oligo(dT) as a template, eliminating the possible presence or induction of terminal deoxynucleotidyl transferase. Our experiments also ruled out either induction or activation of a reverse transcriptase encoded by the host. An RNA-dependent DNA polymerase activity induced specifically in AH22/pAM.ORFV cells was therefore identified as the ORF V-encoded reverse transcriptase.

The specific activity of the ORF V protein produced in yeast by AH22/pAM.ORFV was purified about 4,000-fold over crude extracts, with a yield of 20% (Table 2*a*). During glycerol gradient centrifugation, the enzyme activity sedimented as a single peak of apparent relative molecular mass (M_r) ~70,000 (Fig. 2); this is consistent with the ORF V coding capacity of 78,000. Pfeiffer and Hohn[19] have found that a 79,000-M_r polypeptide in organelles extracted from CaMV-infected turnips showed reverse transcriptase-like activity. The molecular size of our purified ORF V-encoded polymerase in its native condition is similar to that found in the virus-infected turnips. Therefore, CaMV-encoded reverse transcriptase can be active as a monomeric polypeptide, as is murine leukaemia virus (MuLV)-encoded reverse transcriptase (reviewed in ref. 20). However, in contrast to the findings of Pfeiffer and Hohn[19], the purified ORF V-encoded polymerase (glycerol gradient fraction) failed to show any activity on SDS-polyacrylamide gel electrophoresis. Furthermore, because of the very small yield of the purified ORF V-encoded polymerase, it is hard to estimate the size of the polymerase by SDS-polyacrylamide gel electrophoresis.

The purification of the CaMV reverse transcriptase was also monitored by examining the template specificity of the enzyme fraction at each purification step (Table 2*b*). Regardless of the step of purification, substantial activity was obtained by poly(rC)-oligo(dG) as well as with poly(rA)-oligo(dT). CaMV reverse transcriptase was also characterized as a MuLV-type reverse transcriptase by virtue of its activity on poly(rCm)-oligo(dG) and its divalent metal ion requirements[21]. CaMV reverse transcriptase requires 2 mM MnCl$_2$ (instead of 5 mM MgCl$_2$) for maximum polymerization activity, and the reaction proceeds linearly for 2 h at an optimum temperature of 20 °C (data not shown). For reverse transcription with native RNA, for example, human liver messenger RNAs primed with oligo(dT) and tobacco mosaic virus RNA primed with synthetic DNA (25 bases), which is complementary to a 3′ end of the viral RNA, Mn^{2+} was more effective than Mg^{2+} in promoting the synthesis of longer complementary DNA (in preparation), and also for promoting DNA-dependent DNA polymerase activity with native DNA such as single-stranded mp8 DNA primed with synthetic sequencing primer (in preparation). Neither endo- nor exodeoxyribonuclease activity other than

AH22/pAM.ORFV	+	486.0	191.0	13.0

The growth of yeast cells and induction were performed as described elsewhere[15]. Yeast cells were grown in high-inorganic phosphate (P_i) medium at 30 °C with aeration. When the cell density reached $\sim 1\text{–}2 \times 10^6$ cells ml^{-1}, the cells were centrifuged and resuspended in low-P_i medium for induction. Control samples were treated similarly, with the exception that high-P_i medium was used. When the density reached $2\text{–}3 \times 10^7$ cells ml^{-1}, 50-ml samples of induced (+) and non-induced (−) cultures were centrifuged. The cells were suspended in a 15-ml solution of Zymolyase (200 $\mu g\ ml^{-1}$), 1.2 M sorbitol, 50 mM Tris-HCl (*p*H 7.5), 14 mM 2-mercaptoethanol and incubated for 30 min at 30 °C. The spheroplasts were collected by centrifugation and lysed in 2 ml of 50 mM Tris-HCl (*p*H 7.5), 0,1% Triton X-100, 1 mM dithiothreitol. The lysate was clarified by centrifugation at 10,000*g* for 10 min. Protein concentration was measured by the modified Bradford method[26] using a Bio-Rad protein assay kit. RNA-dependent DNA polymerase activity was assayed as described by Marcus *et al.*[27] and Dion *et al.*[28] with modifications. Unless otherwise stated, the reaction mixture (0.05 ml) contained 50 mM Tris-HCl (*p*H 7.5), 50 mM KCl, 2 mM $MnCl_2$, 80 $\mu g\ ml^{-1}$ poly(rA), 10 $\mu g\ ml^{-1}$ oligo(dT), 4 μM ^{3}H-dTTP (3,000–4,000 c.p.m. $pmol^{-1}$), 5 mM dithiothreitol, 0.01% Nonidet P-40 (NP40), 0.1 mg ml^{-1} bovine serum albumin and 9 μg protein of the crude extracts, and was incubated for 30 min at 30 °C. When indicated, poly(rC)-oligo(dG) (90 $\mu g\ ml^{-1}$) or poly(rCm)-oligo(dG) (90 $\mu g\ ml^{-1}$) was substituted for poly(rA)-oligo(dT) and ^{3}H-dGTP (2,000 c.p.m. $pmol^{-1}$) was substituted for ^{3}H-dTTP. Reactions were halted by the addition of 0.1 ml of herring sperm DNA (1 mg ml^{-1}), 0.1 ml of 0.1 M sodium pyrophosphate and 3 ml of 10% (w/v) trichloroacetic acid and kept on ice for 10 min. Radioactivities incorporated into acid-insoluble fractions were counted. ND, not done.

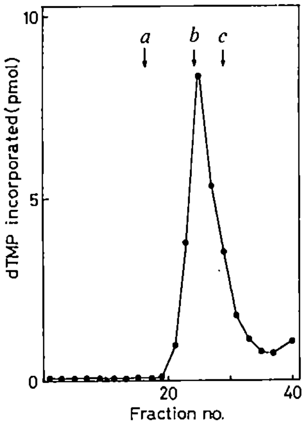

Fig. 2 Glycerol gradient centrifugation of CaMV reverse transcriptase. The enzyme fraction of step III was sedimented through a glycerol gradient as described in Table 2 legend. Aliquots (0.12 ml) of the fractions were collected from the bottom of the tube and 2-μl aliquots assayed for RNA-dependent DNA polymerase activity using poly(rA)-olido(dT) as template-primer. The positions of the marker proteins phosphorylase *b* (M_r 92,500) (*a*), bovine serum albumin (68,000) (*b*) and ovalbumin (43,000) (*c*) in a parallel gradient are indicated.

ribonuclease activities, which seriously affected cDNA synthesis with native RNAs, was associated with reverse transcriptase in a glycerol gradient fraction. This finding might be expected in view of the absence of a putative endonuclease coding domain in CaMV ORF V[22].

We have also attempted to express the CaMV ORF V gene in *Escherichia coli*. The entire ORF V gene, which lacks the first of two adjacent putative initiation codons, was inserted immediately downstream from the initiation codon of the *tac* promoter in the *E. coli* expression vector ptac12. The recombinant plasmid was transformed into *E. coli* NK5830 cells and the resulting transformant, NK5830/ptac.ORFV, was treated with 1 mM isopropyl β-D-thiogalactoside to induce the ORF V product under control of the *tac* promoter. The induction-specific polypeptide with an apparent M_r of 70,000 was found in SDS-polyacrylamide gels (data not shown). The polypeptide was accumulated as 1–3% of the total protein in *E. coli* during an induction of 2 h. The M_r of the polypeptide induced in *E. coli* was nearly the same as that of a native CaMV reverse transcriptase produced in yeast cells. However, in *E. coli*, no reverse transcriptase-like activity was detected, even in the partially purified fractions.

Some other foreign proteins, such as the human hepatitis B surface antigen gene[15,23], have been difficult to express in active form in *E. coli*. It is conceivable that post-translational modification and/or slight processing which is not sufficient to affect the apparent size of the polymerase could be required to produce CaMV reverse transcriptase in active form. For example, a putative protease-coding domain has also been predicted in the CaMV ORF V gene by Toh *et al.*[22]. This putative protease may be required to process a reverse transcriptase to active form in yeast cells. Recently, MuLV reverse transcriptase, of which the NH_2 and COOH termini approximate the correct termini of the authentic protein, has been expressed in active form in *E. coli* cells[24,25]. In the case of our cloning of CaMV reverse transcriptase, we did not leave any coding sequences

Table 2 Purification of ORF V gene product induced in yeast cells (*a*) and template specificity of enzyme fraction in each purification step (*b*)

a, CaMV reverse transcriptase was purified from 50 ml of crude extract (step I, 90 mg total protein). The crude extract was prepared from the spheroplasts obtained from 1.5 l culture of induced yeast AH22/pAM.ORFV cells, as described in Table 1 legend. Step I product was applied to a phosphocellulose column (2 cm × 3 cm) equilibrated with buffer A (50 mM Tris-HCl (*p*H 7.5), 2 mM 2-mercaptoethanol, 0.2 mM EDTA, 0.01% NP40, 20% (v/v) glycerol) containing 50 mM KCl. The column was washed with 30 ml of the same buffer and the enzyme was eluted with a 100-ml linear gradient of 0.05–0.8 M KCl in buffer A. RNA-dependent DNA polymerase fractions (0.4–0.55 M KCl) were pooled and dialysed against buffer A containing 20 mM KCl (step II). Step II product (2.5 mg protein) was applied to a denatured DNA cellulose column (1.2 × 2.5 cm) equilibrated with buffer A containing 20 mM KCl. The column was washed with 5 ml of the same buffer and the enzyme was eluted with a 30-ml linear gradient of 0.02–1.0 M KCl in buffer A. The enzyme fractions (0.26–0.38 M KCl) were pooled (step III). Step III product (0.41 mg protein) was diluted with two volumes of buffer A and applied to a small phosphocellulose column (1.2 × 1 cm) equilibrated with buffer A. The concentration of the enzyme was carried out by stepwise elution with buffer B (50 mM Tris-HCl (*p*H 7.5), 2 mM 2-mercaptoethanol, 0.01% NP40, 0.2 mM EDTA, 10% (v/v) glycerol, 1.0 M KCl). The concentrated enzyme fraction was applied to a 5-ml glycerol gradient (15–30%) in buffer B. Centrifugation was for 20 h at 48,000 r.p.m. in an RPS-50-2 Hitachi rotor at 4 °C. Active fractions were pooled and dialysed against buffer A containing 50% (v/v) glycerol and 1.0 M KCl, and stored at −20 °C (step IV, 0.005 mg protein). After this step, no detectable loss of activity occurred over 3 months at −20 °C. Aliquots of 5 ng–9 μg protein from each step of enzyme fraction were used for the RNA-dependent DNA polymerase assay with poly(rA)-oligo(dT), as described in Table 1 legend. One unit of the enzyme catalysed the incorporation of 1 nmol of dTMP in 60 min at 20 °C. *b*, Each step of enzyme fraction (5 ng–9 μg protein) was assayed for RNA-dependent DNA polymerase using poly(rA)-oligo(dT), poly(rC)-oligo(dG) and poly(rCm)-oligo(dG) as described in Table 1 legend. The incubation time at 20 °C was the same as above except that step I was for 15 min.

between the APase or *tac* promoter and the initiation codon of the ORF V gene in the expression plasmids, and so the products should be a non-fused, complete ORF V polypeptide. This has yet to be confirmed by amino-acid sequence studies.

We thank Dr R. J. Shepherd for pCaMV10, Dr K. Matsubara for the yeast expression vector pAM82 and yeast AH22, Mr T. Noguchi for his help in restriction mapping, and Dr T. R. Broker for his reading of the manuscript. This work is supported in part by Funds for Promoting Science and Technology from the Science and Technology Agency of Japan, and Grants-in-Aid for Cancer Research and for Cooperative Research from the Ministry of Education, Science and Culture of Japan.

Detection of cytosine methylation in the maize alcohol dehydrogenase gene by genomic sequencing

Harry Nick*, Barbara Bowen*, Robert J. Ferl† & Walter Gilbert*

Biogen Research Corporation, Cambridge, Massachusetts 02142, USA
† Department of Botany, University of Florida, Gainesville, Florida 32611, USA

DNA methylation is believed to be involved in the control of gene expression[1,2]. In higher plants, up to 30% of the cytosine residues can be methylated—at C-X-G trinucleotides as well as C-G dinucleotides—compared with only 2–8% of total cytosines appearing exclusively as 5-methyl-C-5-methylcytosine in higher animals[1–4]. We have used the genomic sequencing technique of Church and Gilbert[5] to study the methylation of an alcohol dehydrogenase gene, *Adhl*, from maize. *Adhl* is one of two unlinked maize alcohol dehydrogenase genes[6,7] and appears in several tissues, including the scutellum of the kernel and the primary root of the seedling. It is further induced in primary roots subjected to anaerobiosis[8–10]. However, this gene is totally repressed in maize leaves[11]. Nonetheless, we have now found that a 900-base-pair (bp) region 5′ to the ATG is not methylated in leaves, even though it is rich in potential methylation sites. The first methylations occur 965 bp 5′ to the ATG. Thus, methylation does not appear to be involved in repressing this plant gene.

Restriction endonucleases whose activity is blocked when their recognition site is methylated have been used to detect modified C-G sites in the genome[12,13]. However, even with the ability to use additional enzymes such as *Pst*I and *Pvu*II (ref. 14) for methylation analysis in plants, restriction sites represent a small percentage of potential methylation sites. To demonstrate the applicability of genomic sequencing to the maize genome, which, at $\sim 7\times10^9$ bp, is two to three times larger than the mammalian genome[15,16], we analysed the methylation levels of cytosine residues in the 5′-flanking region of *Adhl*.

Figure 1 illustrates the genomic sequencing strategy. After cutting genomic DNA with a restriction enzyme that acts near a region of interest, the DNA was reacted with hydrazine and piperidine to liberate fragments terminating at cytosine

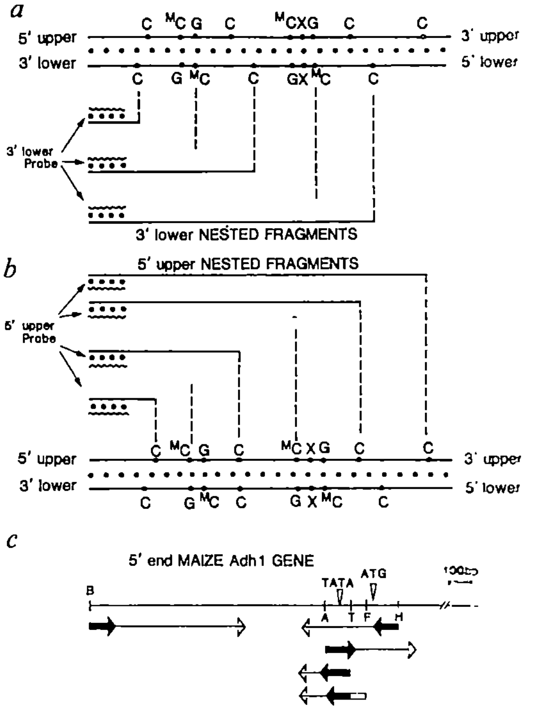

Fig. 1 ***a,*** A double-stranded genomic restriction fragment showing upper and lower strands in a 5′ to 3′ convention. A collection of nested fragments are generated by a partial cleavage with hydrazine and piperidine specific for cytosine residues. Methylation of cytosine prevents reaction with hydrazine so that no fragment is generated which terminates at this residue and thus the corresponding band on a sequencing gel is absent. Four possible strand-specific end-labelled sequences may be displayed. A 3′ lower probe illustrates the detection of the 3′ lower nested fragments. ***b,*** The detection of the opposite strand sequence originating from the same genomic restriction fragment. The hybridization with a 5′ upper probe displays the collection of 5′ upper nested fragments terminating in cytosine residues. Similarly, sequence originating from either the 3′ upper or 5′ lower strands may be displayed with the corresponding 3′ upper and 5′ lower probes. ***c,*** The region at the 5′ end of maize *Adhl* gene probed for cytosine methylation using genomic sequencing. The ATG codon and TATA box are shown by open arrows. The five vertical lines illustrate the position of the genomic restriction sites (*Bam*HI (B), *Hae*III (A), *Taq*I (T), *Hin*fI (F) and *Hin*dIII (H)), from which genomic sequence (thin lined arrow) was derived using the corresponding 100-bp single-strand DNA probes (thick darkened arrows). The open portion of one arrow shows how a probe starting from the *Taq*I site was used to probe *Hin*fI-cut chemically treated genomic fragments.

---

* Present addresses: Department of Biochemistry and Molecular Biology, College of Medicine, University of Florida, Gainesville, Florida 32610, USA (H.N.); Biological Laboratories, Harvard University, 16 Divinity Avenue, Cambridge, Massachusetts 02138, USA (B.B., W.G.).

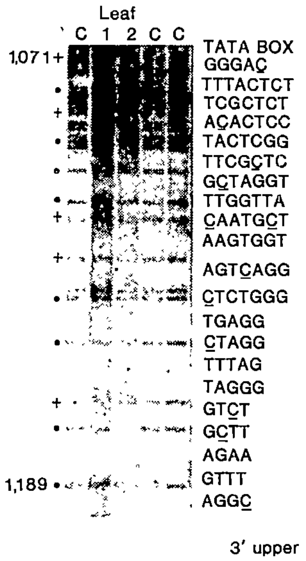

Fig. 2 Genomic sequence originating from the *Hin*dIII site extending towards the TATA box. Lane 1, 50 μg leaf genomic DNA; lane 2, 25 μg DNA. The lanes labelled C are hydrazine reactions on cloned plasmid DNA restricted with *Hin*dIII to illustrate the position of each cytosine residue. The sequence begins at position 1,189 (numbering scheme in Fig. 4) and proceeds 5′ to the TATA box near position 1,071. The dots and crosses denote the positions of cytosines in C-G dinucleotides and C-X-G trinucleotides, respectively.

Methods. DNA was isolated from maize leaves by a modification of published procedures[27]; the nucleus isolation buffer was 0.3 M sucrose, 50 mM Tris-HCl *p*H 8.0, 5 mM $MgCl_2$, 15 mM NaCl; 0.1 mM phenylmethylsulphonyl fluoride, 0.1 mM EGTA and 0.5 mM 2-mercaptoethanol. The crude nuclear pellet was lysed in 50 mM Tris-HCl *p*H 8.0, 20 mM EDTA, 1% sarkosyl and the DNA purified by equilibrium density centrifugation in CsCl. Leaf genomic DNA was digested to completion with *Hin*dIII, reacted with hydrazine and piperidine[17], applied to a denaturing gel, electrotransferred and the nylon ultraviolet irradiated as described elsewhere[5]. The 3′ upper strand sequence is displayed by hybridization with a 3′ upper single-strand DNA probe[5]. We have noted that identical single-copy maize signals may be obtained, with a corresponding lower noise level, when 0.25 mCi of label, rather than 1 mCi, is used. The hybridizations were performed at 65 °C as described above except that some of the filters were hybridized in a lexan tube submerged in water at 65 °C in a new rotating device, which will be described elsewhere (R. Tizard and H.N., manuscript in preparation). Washes were performed as described previously[28]. The membranes were autoradiographed with an intensifying screen for 2.5 days to 2 weeks.

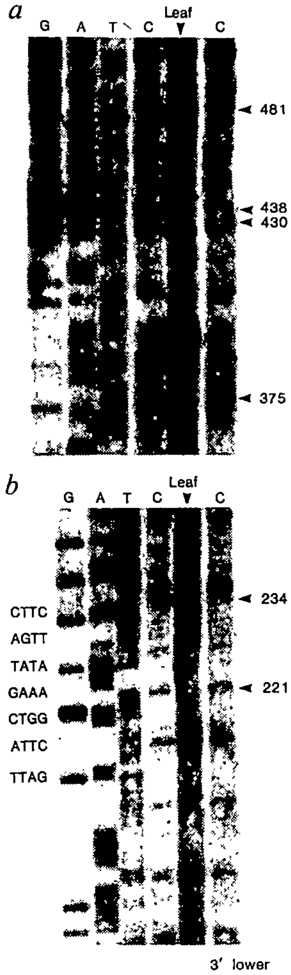

Fig. 3 Genomic sequence originating from the *Bam*HI site 1,200 bp 5′ to the ATG codon. Parts *a* and *b* are from the same autoradiogram. Leaf genomic DNA (30 μg) was digested to completion with *Bam*HI and treated as in Fig. 2. A 3′ lower probe was hybridized with this membrane to display 3′ lower strand sequence, which begins at position 192 and extends 3′ towards position 481 at the top of *a*. *a*, The positions of four potential methylation sites (481, 438, 430 and 375) are shown by the arrows. All of these bands are detectable, as compared with the G, A, T and C reactions on the cloned plasmid DNA. *b*, The next two potential methylation sites (234 and 221) as indicated by the arrows are absent due to cytosine methylation at a C-A-G and C-T-G trinucleotide.

residues[17]. The fragments were then separated on a denaturing gel, electrotransferred to a non-charged nylon membrane and photo-crosslinked to the nylon. Hybridization with an end-specific, strand-specific DNA probe displayed the sequence of the desired genomic restriction fragment (the 5′ upper or 3′ lower probe in Fig. 1[5]). Because 5-methylcytosine does not react with hydrazine, no fragment was generated from this site[18]. In plants, this will result from methylation of either the sequence C-X-G or C-G (refs 3, 4 and Fig. 1*a*, *b*).

Figure 1*c* summarizes the probes used and the region studied. Hybridization with a 3′ upper probe originating from a *Hin*dIII site in the first intron produced the sequence of the 3′ upper strand from a *Hin*dIII digest of leaf genomic DNA. Figure 2 displays sequence from 25 and 50 μg of leaf DNA, flanked by control cytosine reactions from cloned plasmid DNA. The sequence runs out 100 bases to the TATA box and covers 13 potential methylation sites. All of the bands corresponding to C-G to C-X-G sites are present in the genomic DNA, which demonstrates that the 5′ end of *Adhl* is hypomethylated in leaves. Further data (Fig. 4) show that at least 350 bp in the 5′ region are hypomethylated in leaves.

We searched for methylation in an area further 5′ to the gene by probing from a *Bam*HI site 1,200 bp from the gene's ATG codon. Figure 3*a* depicts the 3′ lower strand sequence and the four potential methylation sites; these sites are also hypomethylated. However, Fig. 3*b* from the same autoradiogram reveals two methylated sites 950 bp upstream of the start site, at positions 234 and 221 in the trinucleotide sequences C-T-G and C-A-G. This experiment thus defines a transition in the state of methylation at the 5′ end of the maize *Adhl* gene.

Figure 4 summarizes our data and gives the number of potential methylation sites per 100 bp. We have probed 61 out of 107 of the C-G and C-X-G sites within 1,400 bp surrounding the 5′ end of *Adhl.* For 950 bp flanking the ATG codon, the *Adhl* gene is completely hypomethylated in leaves (with a single gap in our data at position 650–900; Fig. 4). We were unable to find probes that would yield clean sequence across the 650–900-bp region. We attribute this either to the fact that this region and its immediate vicinity are repetitious or that there is a universal nicking of the DNA strands in this region in the nuclear prepar-

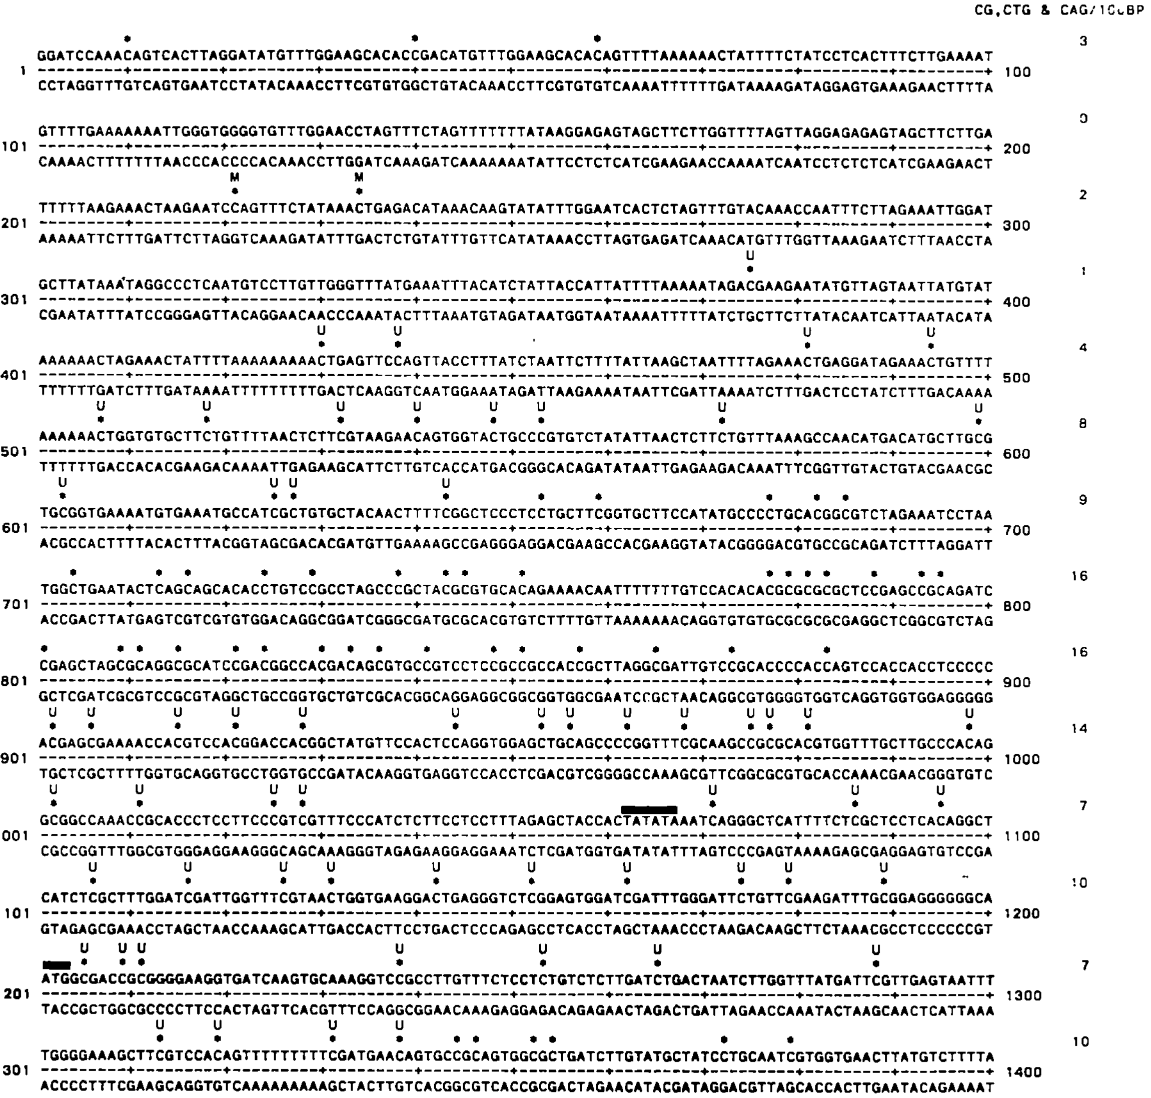

Fig. 4 Summary of cytosine methylation at the 5′ end of the maize *Adhl* gene. An asterisk appears above each potential methylation site in the 1,400 bp of 5′-flanking sequence. Only three types of sites, C-G, C-A-G and C-T-G, are indicated. The TATA box is centred at position 1,065 and the ATG codon at position 1,201, each denoted by a dark line. The U designates sites which are unmethylated and the M sites which have been found to be methylated. A gap exists in our data between sites 650 and 900. Only a small amount of the primary data have been shown; all of the data are illustrated on the top strand for simplicity. The numbers in the column on the right give the number of C-G, C-A-G and C-T-G sites per 100 bp.

ations. We expect this 'gap' to be hypomethylated, since the flanking sequences are uniformly hypomethylated. At 130 bases further 5′, we detect the first cytosine methylation; positions 234 and 221 are completely methylated.

The frequency of potential methylation sites in the first 300 bp of Fig. 4, the methylated region, is 1.3 sites per 100 bp. This is very low compared with the average of 9.3 sites per 100 bp in the next 1,100 bases, which is the statistical expectation and suggests that this last region is never methylated in any tissue and therefore never subjected to the pressures of transition mutagenesis through spontaneous deamination[19-21].

Considerable data have been accumulated using modification-sensitive restriction endonucleases, predominantly with animal genes[1,2]. The major implication of such data is that actively transcribed genes are hypomethylated relative to inactive genes—specifically, C-G sites at the 5′ end of genes[22,23]. The application of methylation-sensitive restriction enzymes in plants has previously been limited to studies of the T-DNA of crown gall tumours, repetitive sequences and 5S RNA genes[14,24-26]. Our results are the first extensive methylation study in plants correlated to a unique gene sequence, *Adhl*, as well as the application of genomic sequencing to a genome as large as that of maize.

Because the 950 bases in front of the gene, in a tissue in which this gene is completely repressed, are hypomethylated, we do not see any role for methylation in the control of expression of *Adhl*. If methylation were to function in repression here, it would do so from a distance of 1,000 bp.

We thank Marty Sachs and W. J. Peacock for sequence data before publication, M. Freeling for the genomic clone and Anna-Lisa Paul for technical assistance. This research was supported by USADA/CARGO grant 83-CRCR-1-1271 and Biogen Research Corporation.

Transcription factor Sp1 recognizes a DNA sequence in the mouse dihydrofolate reductase promoter

William S. Dynan*‡, Shelley Sazer†, Robert Tjian* & Robert T. Schimke†

* Department of Biochemistry, University of California, Berkeley, California 94720, USA
† Department of Biological Sciences, Stanford University, Stanford, California 94305, USA

Human (HeLa) cells contain a host-cell-encoded transcription factor, Sp1, which is required for transcription of simian virus 40 (SV40) promoters[1,2]. Since the discovery of Sp1 we have been interested in learning what role this factor plays in uninfected cells. A monkey cellular gene promoter interacts with Sp1[3], but no gene products linked to this promoter have yet been identified. The finding that the sequence of the 5′-flanking DNA[4] of the mouse dihydrofolate reductase (DHFR) gene contains several regions showing strong homology to the Sp1 binding region of simian virus 40 (SV40) prompted us to undertake experiments with *dhfr*. We report here that Sp1 binds to these regions in the *dhfr* promoter, and that Sp1-containing preparations stimulate transcription from the *dhfr* promoter in an *in vitro* reaction. Our results suggest that in addition to its interactions with the SV40 viral promoter, one function of Sp1 is to direct the expression of the cellular DHFR gene.

DHFR catalyses the production of tetrahydrofolate, which is required for *de novo* synthesis of thymidylate, purines and glycine. The level of *dhfr* RNA varies during the cell cycle, being maximal at the onset of DNA synthesis[5]. Recent studies indicate that the 5′ end of the major *dhfr* messenger RNA lies 55 base pairs (bp) 5′ of the translation start[25] while the previously described −115 terminus[4,5] is a minor species in exponentially growing cells. As with SV40[6] and the monkey cellular gene promoter[7], transcription from the *dhfr* promoter region is bidirectional, with a transcript of unknown function synthesized from the opposite strand[8].

Deletion analysis of the *dhfr* promoter has been used to localize sequences showing promoter activity. DNA sequences within 300 bp of the *dhfr* initiation codon direct sufficient expression for cell survival in selective medium[4]. When partially purified Sp1 from human (HeLa) cell extracts was incubated with an end-labelled *dhfr* fragment containing this promoter region, four discrete regions were protected from DNase I in a footprinting assay (Fig. 1). Each footprint covered 20 bp on each strand of the DNA and included one 'GC box', a decanucleotide homologous to the consensus Sp1 binding sequence (Fig. 1*a*, *b*). To show that Sp1 was specifically responsible for the observed protection, the binding assay was carried out in the presence of several competitor DNAs (Fig. 2). The unlabelled *dhfr* fragment competed for protein bound to the *dhfr* promoter region, and almost eliminated the protection (Fig. 2*a*). A fragment containing the Sp1 binding region of the SV40 gene also reduced protection to a similar extent (Fig. 2*b*), suggesting that the same protein binds to the promoter regions of the SV40 gene and *dhfr*. By contrast, a fragment of similar size containing the adenovirus-2 (Ad-2) major late promoter, which has no Sp1 binding site, had no effect on the pattern of protection (Fig. 2*c*). The reciprocal experiment, where the various fragments were added to a binding reaction containing labelled SV40 probe, gave similar results (not shown).

In vitro transcription of *dhfr* directed by a HeLa nuclear extract was mapped in a runoff assay (Fig. 3*a*). Using two different templates, we saw transcripts (Fig. 3*a*, lanes 1, 3, arrows) of roughly the size expected for RNA initiating at −55, relative to the translational start codon. The position of the 5′ end, 40 bp downstream from the most proximal Sp1 site, corresponds to the pattern seen in SV40 and herpesvirus transcription units (refs 2, 9, 10 and K. Jones, K. Yamamoto and R. T., unpublished; for review, see ref. 11). α-Amanitin (1 μg ml^{-1}) inhibited synthesis, as expected for products of RNA polymerase II. When the *in vitro* RNA was analysed by primer extension (Fig. 3*b*, lane 1), one major group of bands was again seen, corresponding to initiation on the *dhfr* coding strand near −55 (Fig. 3*b*, large arrow); a less intense band was also visible, corresponding to initiation at −115 (small arrow). Several bands of smaller size, present in variable amounts, could represent either RNA initiating downstream of −55, or incomplete complementary DNA products synthesized from the major *dhfr* transcript. A similar primer extension analysis carried out using *in vivo* RNA (Fig. 3*b*, lane 2) produced essentially identical results, showing that the *in vitro* transcription system faithfully reproduced the *in vivo* pattern of RNA synthesis.

These experiments were then extended to a more highly purified transcription system, where Sp1 had been separated from the other enzymatic components required for transcription initiation. Without Sp1, *dhfr*-specific transcription was not detected (Fig. 4). Addition of partially purified Sp1 resulted in a significant activation of transcription. The pattern of Sp1-dependent transcripts was similar to that seen using the unfractionated extract, with a prominent start at the −55 site. As expected, Sp1 similarly stimulated the SV40 gene early promoter, but had no effect on the Ad-2 major late promoter. The *dhfr* template in this experiment was cleaved at −406, indicating that sequences upstream of this position are not required for Sp1-responsive transcription. Preliminary results, however, indicate the presence of additional Sp1 binding sequences in this upstream region. Moreover, in some experiments where sequences upstream to −900 were present, a higher basal level of transcription was seen in the absence of Sp1, reducing the net Sp1 stimulation. These results indicate that additional Sp1-dependent and independent transcription control elements are probably present in the region upstream of −406, and agree with earlier studies showing that this upstream region has promoter activity *in vivo* when fused to the DHFR structural gene[4].

All mammalian *dhfr* genes so far examined contain potential Sp1 binding sites. The mouse[4], human[12] and hamster (P. Mitchell and L. Chasin, personal communication) *dhfr* genes each have at least 5 GC box decanucleotide sequences within the 700 nucleotides upstream of the 5′ end of the mRNA. Although interaction with Sp1 has been confirmed experimentally only for the mouse *dhfr* promoter, the apparent conservation of Sp1 sites provides additional evidence that the binding of this factor has a functional role.

Recent reports indicate the presence of potential Sp1 binding sites in the 5′-flanking regions of cellular genes in addition to

Fig. 1 Binding of Spl to a double-stranded DNA fragment containing the proximal portion of the *dhfr* promoter. *a*, 5′ End of the C-rich strand labelled downstream of +6. DNA sequence markers were prepared by chemical cleavage[21] (far left). Binding reactions contained 0, 3, 6 or 9 μl of Spl as indicated above the lanes. Four discrete regions of protection are marked by vertical brackets on the right. *b*, Same fragment with 3′ end of the G-rich strand labelled downstream of +6. DNA sequence markers and binding reactions are as shown on the left. The promoter region contains four 45–48-bp imperfect tandem repeats; the sequence is written at the bottom (*c*), aligned for maximum homology. Bars indicate areas protected from DNase and boxes enclose GC box decanucleotides. The consensus Spl binding decanucleotide derived from analysis of a number of viral and cellular promoters[22] is:

$$\overset{G}{\underset{T}{}}\text{GGGCGG}\overset{GGC}{\underset{AAT}{}}$$

The map indicates the position of the major mRNA initiation site relative to 45–48-bp repeats; the area marked as promoter is sufficient for *in vivo dhfr* expression. Numbering is relative to the *dhfr* initiation codon at +1.

Methods. DNA was labelled at a linker downstream of position +6, using polynucleotide kinase and [γ-^{32}P]ATP to label the 5′ end of the C-rich strand, or reverse transcriptase and [α-^{32}P]-deoxynucleotide triphosphates to label the 3′ end of the G-rich strand. DNA was cut with a second restriction enzyme in a linker upstream of −406, and the resulting fragment isolated. Pooled Spl fractions from the Sephacryl S-300 column[1] were used in DNase footprinting reactions[2,9]. Binding incubation was at 0 °C, with reactions warmed to room temperature immediately before DNase addition. Reactions contained 18 fmol of labelled probe and 1 μg of native calf thymus DNA carrier.

Fig. 2 Binding of Spl to *dhfr* in the presence of competitor DNA. Three competitor DNA fragments were prepared: *dhfr*, a 412-bp fragment extending from −406 to +6; SV40, a 311-bp fragment (the *Eco*RII 'G' fragment) containing the functional early promoter and Spl binding sites; and Ad-2 P_L, a 290-bp fragment extending from 280 bp upstream of the adenovirus-2 major late initiation site to 10 bp downstream. The competitor fragment and native calf thymus DNA (0.5 μg) were incubated with 0, 3 or 6 μl of Spl for 10 min at 0 °C, then 18 fmol of labelled *dhfr* fragment ('C-rich'; see Fig. 1) was added. The incubation was continued for a further 10 min at 0 °C, then DNase was added and the products were analysed as described[2,9]. The competitor fragment, when present, was in 5-, 10- or 20-fold molar excess over the labelled fragment, as indicated above each lane.

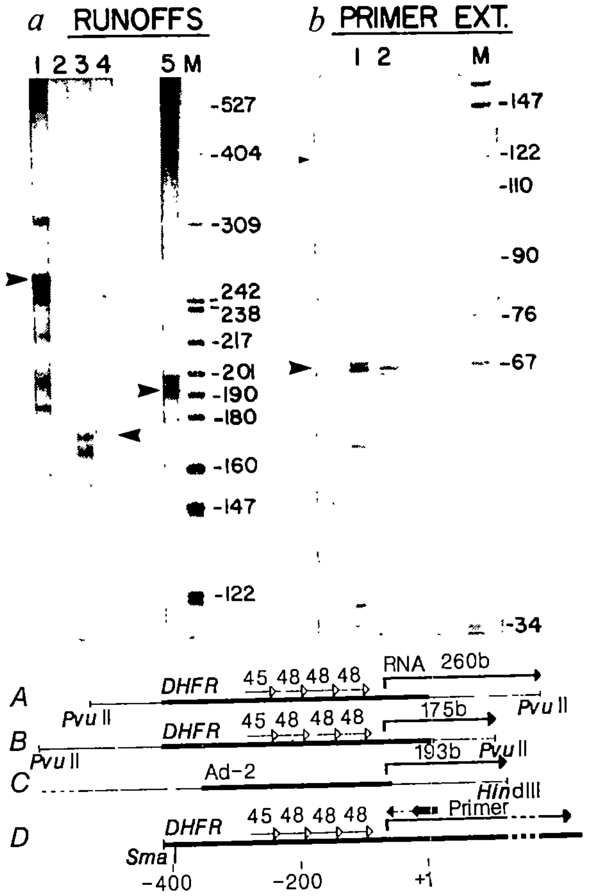

Fig. 3 Transcription of *dhfr*. *a*, *In vitro* runoff transcription. Lane 1, transcription directed by the *dhfr* promoter, template *A* in the diagram at the bottom. The arrow marks the major transcript migrating at 260 bases, relative to DNA size markers. Lane 2, as lane 1 with $1\ \mu g\ ml^{-1}$ α-amanitin. Lane 3, transcription directed by the *dhfr* promoter, template *B*. The arrow marks the transcript at 175 bases. Lane 4, same with $1\ \mu g\ ml^{-1}$ α-amanitin. Lane 5, transcription directed by adenovirus major late promoter, template *C*. The arrow marks the transcript at 195 bases. Lane M, pBR322/*Hpa*II size markers. *b*, Analysis by primer extension. Labelled 24-base synthetic primer has its 5′ end at +11 in the *dhfr* coding region. Lane 1, *in vitro* transcription directed by the *dhfr* promoter, template *D*. The large arrow marks the major extension product, the small arrow the minor product. Lane 2, *in vivo* RNA from nuclei of *dhfr*-amplified cells. Lane M, pBR322/*Hpa*II size marker fragments. *c*, Diagram showing template DNAs. Thick lines, eukaryotic inserts; thin lines, attached vector sequences. **Methods.** Transcription reactions ($50\ \mu l$) contained $15\ \mu l$ of a nuclear extract prepared from human (HeLa) cells[23] and 500 ng of isolated *dhfr* promoter fragment (lanes 1–4) or 1,000 ng of plasmid containing the adenovirus major late promoter (lane 5). Reactions were run as described elsewhere[1]. Runoff reactions contained $50\ \mu Ci$ $[\alpha\text{-}^{32}P]$ CTP and $5\ \mu M$ unlabelled CTP, and were incubated for 60 min. Products were analysed on a thin 5% polyacrylamide-urea gel. Reactions for primer extension contained $250\ \mu M$ nonradioactive CTP and were incubated for 30 min. *In vivo* RNA was isolated from nuclei of *dhfr*-amplified cell line 3T6R50 (ref. 24) as described elsewhere[5]. Hybridization and cDNA synthesis were as described previously[2], and products were analysed on a thin 8% polyacrylamide-urea gel.

dhfr. Several other genes involved in purine metabolism have sequences homologous to the consensus GC box decanucleotides, including those for mouse hypoxanthine phosphoribosyltransferase[13], mouse adenine phosphoribosyltransferase[14] and human adenosine deaminase[15]. Other genes with potential binding sites include rat type II procollagen[16], several members of the human metallothionein family[17,18], human urokinase-plasminogen activator[19] and hamster hydroxymethyl glutaryl CoA reductase[20]. Because there is no known common pattern of regulation for this diverse group of genes, the possible role of Sp1 in their regulation is not immediately apparent. Perhaps the regulatory consequences of Sp1 binding depend on sequences adjacent to the Sp1 sites in a particular promoter, or are the result of interactions between Sp1 and other, as yet unidentified, factors. Further genetic analysis will help to elucidate the physiological role of Sp1 in the regulation of *dhfr* and other cellular genes.

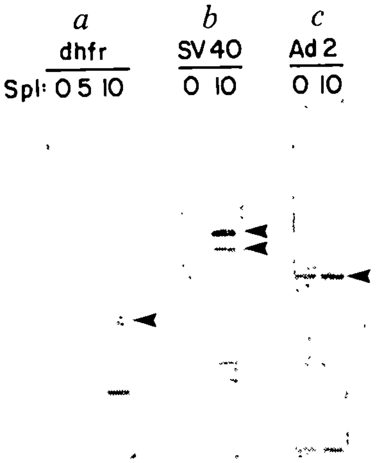

Fig. 4 Sp1-dependent *in vitro* transcription. Reactions contained 250 ng of promoter-containing linearized plasmid DNA, and 0, 5 or $10\ \mu l$ of Sp1, as indicated. Separate complementary oligonucleotide primers were used for each template. Arrow in *a* marks the *dhfr* transcript initiating at about −55. Arrows in SV40 (*b*) and Ad-2 (*c*) mark transcripts initiating at the expected positions. **Methods.** Reactions contained $9\ \mu l$ of endogenous RNA polymerase II fraction and $3\ \mu l$ of transcription factor Sp2, prepared from a whole-cell extract described previously[1]. Sp1 was prepared by a new method (M. Briggs and R.T., unpublished) in which a nuclear extract was passed directly over an S-300 gel filtration column. Pooled fractions had approximately the same specific activity as those pooled from the S-300 column in the previous scheme. Similar stimulation of *dhfr* transcription has been seen with Sp1 fractions prepared by our previous method (not shown)[1].

We thank Pam Mitchell and Larry Chasin for providing the sequence of the 5′-flanking region of hamster *dhfr*. This research was funded by NIH grants to R.T. (CA25417) and R.T.S. (CA16318). W.S.D. was a Senior Postdoctoral Fellow of the American Cancer Society, California Division, Inc. S.S. was a predoctoral trainee supported by USPHS NIH grant GM07276.

nature

NATURE VOL. 319 23 JANUARY 1986

Europe still unsure of itself

The past few weeks have produced yet more evidence that European states are unsure where Europe as a whole is heading. They should make up their minds.

THE great excitement in Britain in the past two weeks about the fate of a small and unsuccessful helicopter company has been presented as part of the struggle for a United States of Europe (see *Nature* **319**, 86; 1986). Mr Michael Heseltine, Secretary of State for Defence two weeks ago, walked out of the British Cabinet for all kinds of reasons, some of which may have been strictly personal, but ostensibly because he said his colleagues in the government were less than fair towards his scheme for letting control of the helicopter company pass to a European rather than to a US-Italian consortium. The general assumption seems to be that those who favour the European bid are true Europeans, and that the supporters of the Sikorsky–Fiat deal, by contrast, are lukewarm or even hostile to Europe. Everybody seems to have overlooked the truth, that the notion that Westland helicopters should be "saved" for Europe by a hastily constructed financial bid is a measure, rather, of the stark inadequancy of Europe's economic integration so far. For in a rational Europe, tears might be shed about the disappearance of a single helicopter manufacturer, but potential purchasers of these machines (of which there are few) would know that there are other companies to which they could turn for supplies.

Much the same applies to the announcement on Monday this (see p.251) week of the agreement between France and Britain that there should be a fixed link across the strip of water that divides them. Officials in Paris have made heavy weather, in the past few weeks, of their attempt to choose one from among the several competing schemes for forging such a link. Because civil servants are not renowned as engineers, it is not surprising that their technical appraisal has been tortuous and that its outcome commands very little confidence. The mere fact that the two governments have been drawn into the adjudication is, however, a confession of the incompleteness of the European programme. In a properly organized Europe, the question of whether private capital should be used to build a bridge, a tunnel or some hybrid of the two would no doubt have been the subject of a public administrative inquiry (since local interest in both countries will be affected), but the technical feasibility of the scheme would have been left to a decision by the markets in which the builders will have to raise the money.

The account on p.255 of the surplus of teachers in West Germany points from a different angle towards the conclusion that Europe is still an awkward compromise between the ideal and the politically possible. For a variety of reasons, West Germany seems to have continued training teachers, many of them specialists who would have taught in high schools, for longer than could be justified by the decline of the birth-rate that seems to have been general in Western Europe during the 1970s. But elsewhere within the European Communities, there are shortages of teachers. Even in Britain, where successive governments have acted vigorously to save public money by cutting back on teacher training and have created a climate in which recruitment to the teaching profession is difficult, there is now the prospect that the acute shortage of science teachers of the past few years will become chronic. Why do not out-of-work West German teachers move to Britain to fill these empty posts? Language difficulties are not a sufficient explanation. Only the general sense that Europe is still an entity largely in name, which affects both individuals and institutions, can explain this immobility in the face of strictly parochial misfortune.

What is to be done? Last week, the European Parliament in Strasbourg gave its blessing to the moderate programme of reform of European institutions that has been negotiated over the past nine months between the governments of the European Communities. The effect will be to remove some of the impediments that now exist to the free movement of goods and services throughout Europe. But the reform is far less radical than some governments (that of France especially) had been crying for last year. It is far less than that required to make Europe an integrated economic unit — yet, even so, there is a chance that Denmark, which is committed to holding a referendum on the issue, will be found blocking this modest programme when it comes for decision in the Council of Ministers later in the year.

If these prevarications and inconsistencies persist, Europe's bluff that it is a continent will soon be called. When the Treaty of Rome that created the European Communities was negotiated in the early 1950s, everybody acknowledged that the new Europe would not spring into being overnight. Now, with more than a third of a century gone, the every-day spectacle of quarrels about the retention of customs posts (one of the matters glossed over in last week's Strasbourg vote) squares badly with proposals such as that of Mr Heseltine that European taxpayers should dig into their pockets to keep a helicopter manufacturer artificially in business for fear of undermining a purportedly integrated European defence industry. United Europe is now not much more than a collection of separate nations agreed to conceal their differences from each other beneath a cloak of even more dedicated extra-European chauvinism. That a united Europe would be an inward-looking Europe has always been a danger; the reality of a disunited xenophobic Europe is an even meaner outcome.

Mercifully, the other side of the coin is now wholly blank. Some European schemes have worked reasonably well. Participants in the Esprit programme for collaborative information technology, for example, say they have won benefits from joint support from Brussels that would not otherwise have arisen. They seem either not to know or not to care that they echo the public statements of participants in the early Euratom programmes of the 1950s, who were invariably well disposed towards unearned income. On this occasion, of course, things may turn out differently. Technological Europeans, in other words, should acknowledge that nothing much has yet been accomplished but that something may be. In other fields, much the same is true; even the freedom of people to move from one place to another only half restores *de jure* what was *de facto* commonplace two centuries ago (when "Europe" was twice as big).

The effective remedy therefore may be the calling of the European bluff. What can Europe do for European voters that national governments do not at present accomplish? The simplest answer is that intra-European trade has increased in the past 30 years, but this makes little sense because it came at a time when world trade as a whole was growing; since the faltering of world trade a decade ago, crises like that at Westland Helicopters have become two a penny. That is why Mr Heseltine's supporters should tell him that while his heart is in the right place, his head is in the clouds; that battling for a united Europe with Westland Helicopters as a slogan is fruitless. Mr Heseltine's local difficulty is that his supporters are not, like him, Europeans by instinct but rather xenophobes. He will not be the first to find himself caught out like that. □

No more numbers game

Last week's Soviet arms control proposals are the best yet, perhaps the best for forty years.

WASHINGTON is still forgivably hesitant and uncertain about last week's proposals on strategic arms control, which are breathtaking in their radicalism. Such a break with the recent past is bound to catch people off guard, which is as it should be. But it would be a great mistake to write off Mr Mikhail Gorbachev's suggestions for what should happen next at Geneva as yet another proposal which, when picked apart, will be found to contain little of substance, or be otherwise objectionable. For the novelty in what Mr Gorbachev had to say last week is his explicit acknowledgement that substantial controls on strategic weapons will not be reached quickly, and that it may take until the end of the century for the abolition of nuclear weapons to be feasible. Previous Soviet leaders have so often impeded rational discussion with impatient demands for "general and comprehensive disarmament" the day after tomorrow that the influence of a pragmatist should be generally welcomed.

The further merit of the Gorbachev plan, with several independent components such as the withdrawal of Soviet and US missiles from the European theatre, a reduction by a half of strategic arms and so on, is that the scheme is plainly not meant as a package but as a negotiating framework. If it is the will of the superpowers to reduce the numbers of strategic weapons they deploy against each other, for their mutual benefit and that of bystanders, it is clear that progress can be made only step by step, and that the first steps must be taken before even the character of later steps is known. The trick is to ensure that none of the intermediate steps will be obstacles to those certain to follow. The negotiators at Geneva are hardly in a position to take such a grand view, which is why there is a need for a response from none other than President Reagan himself.

There are two snags, of which the first is the obvious danger that the future ideal may undermine what is feasible now. It is clearly essential that the goal of abolishing nuclear weapons by the end of the century should not distract attention from tangible steps that could be taken now. The Geneva negotiators who reassembled last week could do worse than settle for a tidying up of the agreements to which they are already parties, SALT II and the Anti-Ballistic Missile Treaty in particular (see *Nature* **319**, 164; 1986), which would seem far from an empty achievement if there is a firm promise of better things to come.

But does the world, or anybody, wish to see the back of nuclear weapons altogether? That is the second snag that everybody must face. The immediate reaction to the Gorbachev proposals from Mr Zbigniew Brzezinski, President Carter's National Security Advisor, that the scheme is a recipe to "make the world safe for conventional war", points to the nub of the difficulty. Nuclear weapons have become so much an aid to the preservation of the *status quo* that even the most farsighted statesmen will think twice before suggesting their abolition. Only the most idealistic or naive believe that the abolition of nuclear weapons could be finally accomplished without agreement on the uses to which conventional forces would be put. But issues like that even touch the degree to which national sovereignty is an autonomous force in international relations. Perhaps it is not too soon to begin asking questions like these, but their difficulty should warn even the optimists that Mr Gorbachev's timetable, worthy though it is, will be much delayed. □

Scribes in space

The US government plans to put a journalist in space later in the year. Is it wise?

SOME years ago, US journalism was enlived by a stocky character with a Brooklyn accent whose career had been transformed by a single assignment, that of being the first journalist to witness in that capacity the explosion of a nuclear weapon at a Pacific atoll. William L. Lawrence by birth, he was known to everybody as "Atomic Bill", and required by the expectations of his companions and editors to fill the role, whatever his inclinations may have been. For decades afterwards, no nuclear reactor could go critical, no diplomatic conference on the future of nuclear energy could take place, without his presence. Only when he retired from the *New York Times* to a Mediterranean island was Atomic Bill able to follow his chief interest, pre-nucleic acid biochemistry. But now, with characteristic indifference to the lessons of history, the National Aeronautics and Space Administration (NASA) is about to wish a similar fate on another unsuspecting journalist, the first ever to be sent up by shuttle.

By the closing date for applications last Thursday, the US Association of Schools of Journalism and Mass Communication, rising to the only occasion in its history likely to be remembered generally, was said to be swimming in a large proportion of the 4,000 application forms requested by aspiring Orbit Micks (or Megs, as the case may be), many of them turned in, in the best traditions, right on deadline. It is hoped that not too many readers will cancel their subscriptions because none of the members of *Nature*'s staff who satisfies the condition of being a US citizen will also meet the requirement of having been in journalism for five years. But there are more onerous conditions.

The worst is that the unlucky winner of the competition will have to work as a one-person "pool", a kind of communal resource to be exploited by all his or her natural competitors, who will be free to demand answers to whatever questions come into their heads. ("Say, *that* nausea, is it worse when you move about?") With NASA in charge of all communications, the pool reporter's traditional ingenuity in keeping the best scraps of information for his own employers will be fully tested. NASA's demand that the reporter should "not intrude on the private lives" of his companions "without their express permission" will not easily be satisfied. It will be irksome that personal equipment that cannot be "flight-qualified" will have to be replaced by what NASA thinks best. The summer in Houston is not everybody's idea of bliss.

Who will be chosen? This is where the fun will start. The medical examination seems not much of a hurdle. The need for a security clearance may be a more serious obstacle even though NASA promises that recruitment will not be based on "political associations or beliefs". But the real fun starts with the two "essay questions" that applicants must answer. One whole sheet of blank paper awaits the response to "How will you attempt to fulfill" the purpose of communicating the "unique experience of space travel"? Maybe the selection panels, representing as they do the schools of journalism and mass communication, have ways of telling when people who fill this sheet with phrases like "mankind liberated from tedious Earth" will lapse, in the event, into phrases like "I can see Paris, France!" But the trick question is the second, which asks that the chosen journalist should speculate, "looking 10 or 20 years into the future", about the value to journalism of the facility "to report regularly from space". It is as if a restaurant were to offer free dinners to those with interesting opinions on the value of dining out. Cruelly, NASA retains the right to publish these essay questions, ensuring that it can ruin not just the career of its equivalent of Atomic Bill, but all those who answer this question with a straight face. □

Archaeologists

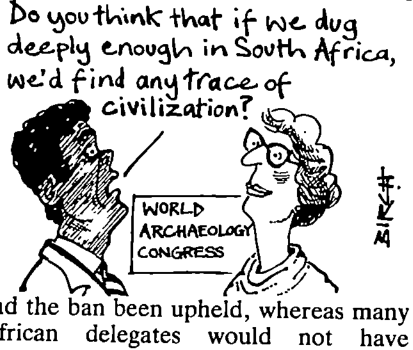
World congress quits Southampton for Mainz

The University of Mainz (West Germany), rather than Southampton (England), will host the 11th World Archaeology Congress in September 1986. The executive committee of the International Union of Prehistoric Sciences (IUPPS), at an extraordinary meeting in Paris last week, took the unprecedented step of "withdrawing recognition" of the congress from the University of Southampton.

Professor John Evans, chairman of the executive committee and president of IUPPS, resigned his position during the Paris meeting, but is to stay on as an ordinary member of the executive. Professor Peter Ucko, organizer of the Southampton congress, ceased to be a member of the executive after the decision to remove the congress from Southampton and left the Paris meeting before it ended.

IUPPS's decision resolves the bitter dispute caused by the banning of South African delegates, including scientists of other nationalities who work in South Africa, from the Southampton meeting (see *Nature* **317**, 754; 1985). The ban resulted from pressure by Southampton's city council and university teachers' and students' trades unions, although Ucko argued strongly against it.

More than 200 participants from the United States, as well as the delegations from France, West Germany, The Netherlands, Belgium, Switzerland and Spain, would have boycotted the meeting had the ban been upheld, whereas many African delegates would not have attended had the ban not been introduced. The IUPPS executive took its action because the organizing committee of the Southampton meeting had departed from IUPPS's statutes and longstanding policy to keep all its activities open to all "*bona fide* scholars". For more than 50 years, the 10 congresses sponsored by IUPPS have been organized on this basis and scholars have been admitted irrespective of race, nationality, religion or political convictions.



Do you think that if we dug deeply enough in South Africa, we'd find any trace of civilization?
WORLD ARCHAEOLOGY CONGRESS

The new president of IUPPS and chairman of the executive committee is Professor K. Böhner of Mainz, and Dr K. Weidermann is the organizing secretary. Notice of the decision to move the congress is to be sent to the members of the permanent council of IUPPS for approval by postal vote.

Professor Phillip Tobias, a member of the council, said in Paris this week that the action "constitutes a landmark decision in the history of the struggle for the freedom of science and for the free circulation of scientists. . . .The IUPPS resolutions constitute a striking reaffirmation of the need to keep scientific intercourse and the access to knowledge free from political, racial or geographical limitations."

Maxine Clarke

Searle's UK research lab closes

G.D. Searle, the US drug company, is to end its pre-clinical research programme in the United Kingdom by closing its High Wycombe laboratories with the loss of 300 jobs. The decision was made largely to avoid a "duplication of effort" in company laboratories in other countries and is part of a worldwide reorganization of the company in the wake of Searle's recent merger with the giant US chemical company Monsanto. At that time, Searle said that the research enterprises of the two companies would reinforce each other.

Much of Searle's UK research effort will be absorbed by Monsanto's directly comparable biotechnology research institute in St Louis, Missouri; the rest will go to Searle laboratories in Belgium and France. Staff will be offered transfers on an "individual basis".

Searle's decision to stop its UK programme stems partly from its disillusionment with the British government's recent regulations designed to save money on National Health Service drugs prescriptions. British-owned companies get a better price for drugs than foreign companies. But a company spokesman stressed last week that Searle will spend more this year on research and development worldwide than ever before; $160–170 million in 1986 compared with $130–140 million in 1985. And individual projects in universities, for example a £1 million project at the University of Oxford, will continue. Searle is now looking for a new site in High Wycombe for its business operations — the present laboratories are considered "unsuitable" for that purpose. Maxine Clarke

Channel tunnel

Rail plan gets go-ahead

After nearly two centuries of talking, Britain and France are to be linked by a tunnel under the English Channel (*La Manche,* the "sleeve", to the French). A historic moment? Not to judge by the French media, which have taken very little interest in the prospect of getting from Paris to London in three and a half hours rather than five.

This is understandable. Through the tunnel, Britain sees the whole of Europe: France sees only Britain. And what do the French think of Britain? In a recent poll by a French science magazine, readers were asked with which country they would like to see French industry and scientists cooperating in high technology. Nearly 30 per cent said West Germany. Only 1 (yes, 1) per cent said Britain.

But, notwithstanding popular French indifference, Prime Minister Margaret Thatcher and President François Mitterrand announced on Monday that construction can now begin of a twin-bore rail tunnel, though which trains will carry freight direct and cars piggy-back. The rail tunnel should be open by 1993. This looks like defeat for the "road" lobby, Mrs Thatcher included, although the winning consortium, the Channel Tunnel Group (CTG), will be asked to prepare plans for a twin road tunnel to be built within fifteen years — if it appears economic.

The decision has not pleased those placed either side of the tunnel. The mayor of Calais, the principal French ferry port, has said that within a few years of the opening of the tunnel Calais would become "a ghost town". That might be true, and the same for Dover, if the rail tunnel provides transit at costs much lower than the ferries, as predicted by CTG's chairman, Sir Nicholas Henderson. A spokesman for the now-defunct "Euroroute" bridge scheme, however, claims that drilling problems and heating and ventilation of a tunnel will force up costs far beyond those now predicted.

A more optimistic scenario, however, has it that the "chunnel" will indeed reduce transit costs, and thus encourage new industries to set up near the tunnel entrances. However, the zone south of the tunnel (in north-east France) may well prove more attractive than that north of it (in Kent and Sussex), as the former will also provide a crossroads for traffic moving east and west across Europe.

French rail interests are also keen on the prospect of running the advanced French high-speed train, TGV (*Train Grand Vitesse*) to London. In many ways, it seems, Monday's decision looks like a French success. **Robert Walgate**

Japanese science budget

Some gains, some losses

Tokyo

BESIDES some big funding increases for a handful of key projects, there is little good news for scientists in the 1986 budgets of two of Japan's major science ministries, the Science and Technology Agency (STA) and the Ministry of International Trade and Industry (MITI).

This year, as for the past few years, the government has done everything it can to cut the size of the budget. What makes this necessary is the enormous fiscal deficit, proportionately just as big as that of the United States. And despite Japan's booming economy, the alternative of raising taxes is no more popular in Japan than in the United States. All ministries are under pressure to make cutbacks and the fact that there have been small increases for science reflects its high priority. The small gains in research and development budgets are in fact scarcely enough to cover inflation. But that has not stopped the launching of new projects and the concentration of funds in key areas.

Within STA's budget, the biggest leap of all (a 750 per cent increase) is seen for the construction of a bathyscaphe capable of diving to perhaps 6,500 m. The plan to build such a vessel — at present only France and the United States have a bathyscaphe capable of going that deep — has been around for many years. With the succesful completion in 1981 of Shinkai 2000, which can reach 2,000 m, it has become a logical step. The new vessel will allow direct observation of the deep troughs off Japan where many earthquakes originate.

Another major budget increase is for planning of a module to be attached to the US space station. The budget is still not large in real terms, however, and if the project is delayed by the United States it may not prove too unwelcome to the government. If the module is built, a major use will be the manufacture of new materials in a gravity-free environment. MITI has launched a new project on this subject with an initial budget of 200 million yen. Interest from industry is strong enough that it may find it has a commercial competitor one day: the Taisei construction company is thinking of building a gravity-free environment on Earth. The trick is to carry out the manufacturing process in a capsule in free-fall down a deep mine, or from the top of a tall building.

Japan's science budget

	Yen (thousand million)	Percentage increase or decrease
Science and Technology Agency		
Research and development budget	427.8	+1.6
Special promotion funds	7.9	+8.2
Space	94.5	+3.3
Nuclear Energy	277.7	+4.2
Ocean Research	7.4	+7.3
ERATO	2.8	+4.6
Ministry of International Trade and Industry		
Research and development budget	197.0	+4.4
Agency of Industrial Science and Technology	113.4	+0.2
Basic technologies for future industries	6.5	+0.1
Large-scale industry	15.2	+3.4
Sunshine project	43.0	−1.9
Moonlight project	12.3	+10.8
Fifth-generation computer project	4.5	−6.3

Another area of space research where Japan is aiming to acquire expertise is the construction of the H-II rocket. Although Japan's large launch vehicles have so far been mainly built under licence, STA's H-II is seen as competing with Ariane and the space shuttle for commercial satellite launches towards the end of the century. This year its budget has leapt by nearly 300 per cent.

Another growth area for STA is in a project to build a heavy-ion accelerator to treat cancer. Funds available for basic research grants are also up, although not by such a huge percentage, and some new funds are available for "frontier research". These confirm STA's role as a supporter of small-scale basic research — a position traditionally held by the Ministry of Education, Culture and Science — as well as a supporter of "big science", space, nuclear energy and the like.

MITI's budget shows continuing support for its large-scale projects — the Sunshine project to develop new energy sources, the Moonlight project to cut energy waste, particularly in large-scale manufacturing, and the set of industrial technology projects. A new theme to be added to the "Basic technologies for future industry project" is that for bioelectronics. Although application is a long way in the future, there has been considerable interest from several large companies, including NEC. Interest stems from twin beliefs that computer manufacturers can learn from the structue of the nervous system, which is why MITI's industrial research agency supports physiology research, and that biological systems might be worth studying as the ultimate in miniaturization.

One project that is not growing as originally planned is the Fifth Generation Computer Project. The belief seems to be that the project's limits are not being set by financial resources but by human ones — there is not enough expertise available to justify further massive spending at present.

Alun Anderson

Space research

Texas A & M fly space-grant kite

Washington

TEXAS A & M University, in an attempt to fill what it sees as a vacuum, is pushing for the creation of a space-grant programme, modelled on the concept of the land-grant and sea-grant programmes. If Texas A & M has its way, it will add space-grant to its land-grant and sea-grant designations.

The sea-grant programme, started in the late 1960s, is a cooperative effort between universities, industry and government to provide financial support for research and public information. The space-grant programme would extend this to include space-based research, as well as research performed on Earth to support long-term projects in space.

Frank Vandiver, president of Texas A & M, sees the space-grant programme as "a good way for government to maximize research dollars". Federal dollars should encourage participation by private industry in university projects, and the financial benefits of the collaboration should be shared by all. That, at least, is the idea.

The land-grant concept has had a profound effect on US higher education. In 1862, the Morrill Act provided federal lands to the states as an endowment for colleges teaching the mechanical and agricultural sciences. The emphasis on applied sciences was reinforced by later legislation providing for research activities and extension services for the dissemination of newly gained knowledge. The triad of teaching, research and public education forms the basis for most modern universities. The original land endowments now amount to less than $3 million in university support, but the research and extension services are supported at levels reckoned in thousands of millions of dollars.

Whether space grant is a truly practical idea is unclear. The sea-grant programme's annual appropriation, this year $37 million, is routinely eliminated from the budget by the Reagan administration, only to be restored by congressional supporters such as Senator Lowell Weicker (Republican, Connecticut). A space-grant programme would be yet another financial burden. Vandiver insists that the initial burden would be more than paid off by applications of sponsored research. He has persuaded Senator Lloyd Bensten (Democrat, Texas) to introduce legislaon establishing a space-grant programme, although the Gramm–Rudman Act (see p.254) makes new spending programmes unattractive.

Some see the space-grant idea as a ploy to increase visibility in an era of tight budgets. But Vandiver insists "it is no flight of fancy with me".

Joseph Palca

Television

Defence of the realm

If further proof were needed that the British establishment is very cool to the idea of Europe, it came last week in the House of Lords report on international television. In answer to the European Commission's proposal to remove some of the restrictions on the flow of television across international barriers, the Select Committee on the European Communities responded with a disdain that can only keep the barriers up.

Not that the lords object to the objectives behind the European Economic Community's green paper of May 1984: *Television Without Frontiers*. Those are unimpeachable: to create a common market in television programmes and to create a sense of European identity. Nor would the subcommittee on energy and technology which took evidence for the report and included Lord Swann (former chairman of the British Broadcasting Corporation) and Lord Zuckerman wish to be seen to oppose the principle of free flow of information, still less to be trying to stop the advance of technology. The report recognizes the inevitable: broadband cable networks and direct-to-home satellite broadcasting will eventually blanket Europe. But the report's conclusions boil down to delaying tactics — not now, not here, not that way.

In fact, the Commission's own proposals to which the lords were objecting are quite modest: that members of the European Community countries come to an agreement on some common advertising standards (to remove such absurdities and barriers to television exchange as the ban on petfood advertising in Italy and on contact lens commercials in Britain). They would also impose a quite relaxed limit on the total amount of programming time (20 per cent) that might, within the Community, be devoted to advertising. They also proposed a possible way through the copyright thicket. As copyright agreements are bound by national borders, it is nightmarish for writers, producers, musicians to try to negotiate the rights for their programmes to be shown in another country or, in the case of Britain, on the mainland of Europe at all. US experience suggests that the new approach to the problem can only come through blanket licensing arrangements; the days of negotiating for each individual transaction disappeared with the arrival of the audio and video tape.

The lords committee, however, firmly rejected every proposal. Rejected in turn were: restricting television advertising time (that could inhibit new kinds of advertising channels); adopting a blanket copyright procedure (that would deprive copyright holders of their freedom). The lords even rejected as unacceptable or unworkable two things the green paper did not propose: a total ban on alcohol advertising and a statutory right to reply for aggrieved parties. In sum, they found the Community the wrong body to regulate and said, contradictorily, that its proposed regulations were both premature and unnecessary as "viewers' freedom to choose will inevitably take the place of regulation".

The committee's strongest point was to argue that the Community is too small (even with 12 members) to adopt such regulations. If the new television environment has satellite signals disregarding all national boundaries, certainly wafting all across Europe, any code that ignores Austria, Norway and Switzerland will not mean very much.

In its confident nationalism, the lords' report sounds remarkably similar to the view of the BBC, the Independent Broadcasting Authority and the European Braodcasting Union. It has fallen victim to the besetting European sin of thinking that in really vital areas (telecommunications procurement is another) national is best — particularly in broadcasting.

But the report, with the notable exception of its evidence, (one of the best summaries available of the hard-to-get information on the status of cable and satellite television in Europe) smacks of Little Englander thinking. The new standards would be minimum, not mandatory. If Britain wanted to restrict its own broadcast television to seven minutes an hour, it could still do so.

British broadcasting is probably the best in the world and regulation of the domestic product can keep it that way. But outsiders' television is crowding in. The Community's proposals are a step toward accepting that fact, and the even more uncomfortable one that if Europe is to become a real community, television programmes should be as free to travel as are workers. **Brenda Maddox**

Television Without Frontiers (HL 43). House of Lords Select Committee on the European Communities: 4th Report 1985 86 HMSO, £12.

UK public spending

No pre-election sweetener

Hopes that the restraints on British research and education spending might be relaxed with the approach of the next general election (due no later than mid-1988) were dashed last week, with the publication of the government's estimates for public spending in the next three years (to April 1989).

The cash value of the science budget, mostly spent by the research councils, estimated at £585 million in the current year and due to rise by £15 million in real terms in the next year, will reach a total of £650 million in 1988–89, an increase that will be eaten away by an inflation rate of 3.5 per cent a year. The cash value of the government subvention of the universities over the same period similarly increases by just 10 per cent.

In spite of the pressures of the past few years, the British system of higher education is not yet actually shrinking, but has stabilized at a total of 484,000 students. Within this total, a decline in university student numbers of roughly 5 per cent (to a total of 256,000) has been offset by the steady growth of the polytechnic system. The government's white paper says that the "participation rate" (the proportion of the annual age group entering higher education) has risen to 14 per cent and will continue to increase for the remainder of the decade.

On research, the government says that its aim is "to maintain and enhance the strength and quality of the science base". The document says the government believes there is further scope for "greater concentration and selectivity", with more emphasis on value for money. The document includes a number of examples of British inventions that have been commercialized successfully, including the synthetic pyrethroids and the cephalosporins. The details of how funds will be distributed among the research councils will be settled, year by year, by the Advisory Board for the Research Councils.

Meanwhile, it seems plain that the squeeze on research will continue in those departments of state that have it within their control. Last year's decision by the Ministry of Agriculture, Fisheries and Food (MAFF) to cut back on research is the chief reason why agricultural research has been forced to continue cutting back on the work at its institutes; last week's document makes it plain that there will be no reprieve, for total spending is to be reduced to £90 million three years from now from the present £95 million, inflation notwithstanding.

Even defence research, the British government's chief outlet for research money in the past, will not be immune. Last week's statement shows that defence research and development spending will have fallen from 13.4 per cent of the total in 1979–80 to 12.8 per cent in the current year (when total UK defence spending is estimated at £18,222 million). □

The Government's Expenditure Plans 1986 – 87 to 1988 89 (House of Commons 9702 – I & II, HMSO, Vol. I £4.80. Vol. II £20.)

Gramm–Rudman Act

Automatic cuts threatened

Washington

WASHINGTON bureaucrats are slowly waking up to the uncomfortable realities of the Gramm–Rudman deficit reduction act approved by Congress at the end of last year. A comparatively modest 4.3 per cent across-the-board cut in non-defence spending for the current fiscal year will, barring some extraordinary legislative contortions, take effect on 1 March, together with a 4.9 per cent cut in defence spending, the saving will be $11,700 million. But that is only a foretaste of the act's potential to wreak havoc. In order to avoid much larger cuts in future, totalling more than $60,000 million in 1987, Congress is steeling itself for some uncharacteristic self-discipline.

The Gramm–Rudman Act seeks to eliminate the federal budget deficit, which was to amount to $220,000 million this year, in five equal annual steps. If the President and Congress can agree each year on a budget that meets that year's target, all well and good. If not, the act mandates "sequestrations" to bring the deficit into line with the target. Defence spending has to carry half of the cuts, and there are exemptions for social security and welfare programmes.

The legislation has fundamentally changed the nature of the political game in Washington. Before, interest groups within the government could try to use their influence to secure their desired level of funding without much fear of adverse consequences. Now, they are having to learn that failure to agree would take the matter out of their hands. The first taste of serious deficit cutting will come next month when President Reagan delivers to Congress his proposed budget for 1987, which will attempt to meet Gramm–Rudman's $144,000 million deficit target and so avoid automatic cuts.

Dr John McTague, acting director of the White House's Office of Science and Technology Policy, was nevertheless taking an optimistic view last week of the prospects for research. McTague pointed out that this year's 4.3 per cent "cut" was on a base already 7 per cent above last year's. As for future years, McTague said basic research had always been one of President Reagan's top priorities and observed that "we have a remarkably consistent President". McTague justified the President's decision to exempt the Strategic Defense Initiative (SDI) from cuts this year on the grounds that SDI "serves a different purpose" from other research.

National Science Foundation (NSF) officials are similarly cheerful, with good reason. The President's 1987 budget request includes a healthy 9 per cent increase for the foundation over last year's total of $1,524 million, which is likely to cause envy among less fortunate agencies. NSF is praying that Congress will manage to pass a budget that avoids the need for Gramm–Rudman's across-the-board cuts next year, which could at a stroke change a 9 per cent increase to an estimated 10 per cent decrease. Erich Bloch, NSF's director, last week termed the automatic cuts provision an "unintelligent" approach to budget planning.

The National Aeronautics and Space Administration (NASA) is in a much less comfortable position. This year's 4.3 per cent cut could lead to lay-offs and even the postponement of shuttle missions unless Congress passes legislation allowing NASA to transfer funds between its four main accounts, research, flight operations, salaries and facilities.

Looking to the future, the brunt of the savings being sought will fall on the space station, leading to a delay of 2–3 years for the project. NASA officials do not deny reports that despite an original 1987 budget request of $580 million, the Office of Management and Budget is unwilling to countenance anything above $100 million.

The National Institutes of Health (NIH) are as yet undecided about how they will cope with this year's cut. But it seems likely that they will try to avoid cutting back on numbers of grants, and instead reduce the size of the cheques.

Each of the various institutes will have to reduce its budget by 4.3 per cent in total, but directors will have discretion to redistribute funds within their own budgets to minimize disruption. NIH officials seem not to have thought seriously about what they would do if faced with large cutbacks next year; NIH usually end up with far more than the administration requests anyway.

Non-nuclear research at the Department of Energy (DoE) will be hit hard, with cuts in 1987 of more than 50 per cent from this year's total of $700 million.

The Department of Agriculture says it will not have much difficulty in achieving 4.3 per cent cuts in the Agricultural Research Service this year, and that savings from vacant posts will probably account for many of them. But if across-the-board cuts are required in 1987 the results will be "too horrible to contemplate".

Many officials and congressional staff admit privately to doubts about whether Gramm–Rudman can survive for long: the savings sought are unprecedented in recent history. But while it may at some point be struck down on constitutional grounds, or simply eroded away by exemptions until it becomes meaningless, in the short term its effects will be real enough. **Tim Beardsley**

Genetic engineering

Frost damage tests blocked

Washington

A NEW set of regulatory hurdles is impeding plans by Applied Genetic Sciences (AGS) of Oakland, California, to release bacteria, genetically altered to protect strawberry plants from frost damage, into the environment.

The problem now lies with the local government in Monterey County, California, where AGS plans to conduct its field trial. Sam Karas, chairman of the Monterey County Board of Supervisors, says residents are unhappy that the first trial is being conducted in a densely populated region. Local citizens are also upset at having no say in the matter. The board is seeking ways to block the trial until local concerns can be dealt with.

In addition, the Monterey Bay Unified Air Pollution Control District wants to see a detailed environmental impact statement before allowing the test to proceed, and has threatened legal action to block the trial if the information is not forthcoming.

The local furore has taken AGS by surprise. Despite the difficulty in obtaining federal approval, Douglas Sarojak, AGS director of product development and marketing, maintains that his company "did not realize the sensitivity to the issue". He adds, "We're scientists, not public relations experts."

AGS won an experimental use permit for its new strain of *Pseudomonas syringae* from the Environmental Protection Agency (EPA) on 14 November after a long struggle (see *Nature* **318**, 96; 1985). The genetically altered bacteria lack a segment of the genome coding for an ice-nucleation protein responsible for frost damage to plants. The new strain will protect plants for competing with wild-type bacteria for positions on leaves.

The local controversy has taken on an international flavour. Karas reports that members of the board of supervisors have received telegrams from members of the Green Party in the West German Parliament as well as from members of the European Parliament urging them to oppose the tests. The board plans to hold a public hearing on 27 January to give all sides a chance to air their views.

Even if AGS receives permission from the local authorities, it may still not be able to proceed. The Foundation on Economic Trends in Washington led by Jeremy Rifkin has a suit pending in federal court seeking to overrule EPA approval of the experimental use permit for *P. syringae*, and Rifkin has gone to court to seek a temporary restraining order to prevent the field trial from starting before the lawsuit is settled. **Joseph Palca**

Soviet Union

Scientists facing redundancy

Most Soviet scientists will henceforth be paid in accordance with their job and performance. A recent joint decision of the Central Committee of the Communist Party of the Soviet Union, the Council of Ministers and the All-Union Central Council of Trade Unions approved new procedures and pay scales that will apply to more than half of all scientists and over 90 per cent of designers and technicians.

Although the new scheme has been presented as part of the Gorbachev package of reforms aimed at streamlining the economy, criticism in the Soviet media of the old system goes back a number of years. Under a set-up in which jobs and salaries depended strictly on academic qualifications and length of service, many scientists in the 35–45 age group, holding the degree of Candidate of Science (roughly equivalent to PhD), were actively or passively discouraged from improving their qualifications by taking a doctorate of sciences. In many cases, acquiring a doctorate would mean seeking work in another town, with consequent disruption to spouse's career and children's education. Scientists who wished, for their own personal satisfaction, to take a higher degree, and who were in some cases willing to continue temporarily in their old jobs and at their old salaries, were told that this would be detrimental to work discipline.

Under the new system, a degree or engineering diploma will be merely one of several criteria determining job and pay scales. From now on a scientist's pay will depend on the effectiveness of his or her research, its scientific and economic importance, and what Valentin Kharin, a senior official of the State Committee for Labour and Social Problems, described in an interview with the Moscow weekly *Literaturnaya Gazeta* as "personal impact" in getting concepts implemented in the economy. (The gap between research and implementation is a longstanding problem to the Soviet planners.) In particular, technicians and engineers without an academic degree seem likely to benefit. According to Mr Kharin, the new scheme will allow them to earn up to 350 rubles monthly, instead of the present maximum of 190 (the national average is around 170 rubles a month).

The new scheme makes likely the redundancy of up to 10 per cent of the present scientific work-force, with, Mr Kharin admits, some difficulty in finding new jobs for those who are dismissed. People who do not work, or who work badly, are liable to find themselves out of a scientific post, regardless of their length of service, he said. This is a remarkable development in Soviet terms. Unemployment was officially abolished in the Soviet Union more than 50 years ago, and people without work are liable to find themselves facing prosecution for "parasitism" — being without visible means of support.

Compulsory retirement of senior scientists may be one way of weeding out the superfluous work force. Already, in Uzbekistan, the President of the local Academy of Sciences, Dr Abid S. Sadykov, has been eased out of his post. According to the Uzbek republic daily *Pravda Vostoka* (22 November 1985), by continuing in office for several years after health and age (he is 72) made him unfit for duty, Sadykov had, by default, allowed corruption, nepotism and general slackness to creep into his academy. *Pravda Vostoka* noted disapprovingly that the average age of Uzbek academicians (75) is far too high and that more room should be made for younger talent. If this trend spreads, it could have important consequences for Soviet participation in world science. Attendance at foreign conferences has until now been viewed by the Soviets principally as a reward for long and faithful service. The Gorbachev efficiency drive could therefore produce a more flexible approach to foreign travel for younger scientists.

Vera Rich

West German schools

Teachers swell dole queues

Hamburg

Unemployment among West Germany's schoolteachers has become a scandal. The number has now reached 100,000, and is continuing to rise. The social cost is very large, given that a qualified teacher will have spent an average of six years at university, as well as perhaps two years at school practice (Referendariat).

Because of the waiting period of a year to eighteen months between university and Referendariat, the average age of qualifying teachers is as high as 30. Yet teachers are almost completely dependent on the state for jobs, in the person of the Kulturministers (the ministers for culture, education and church affairs) of the *Länder*. Fewer than one per cent of all teaching positions in West Germany are in private schools.

Several attempts are being made to solve the problems, but they are too late to help most teachers. Yet the present situation could have been foreseen many years ago from the crudest statistics. The Kulturministers had themselves published several documents giving calculations and predictions for the trends in supply and need of teachers, but nothing was done to prevent catastrophe. Until 1980, every newly qualifying teacher was assured of a post almost automatically. As civil servants, West German teachers are promised lifelong tenure.

The overproduction of teachers resulted from a campaign during the early 1970s when a shortage of schoolteachers of every type was emphasized. Too many students elected to become teachers, even when it became obvious that the shortages no longer existed. Even now, there are still too few teachers in some subjects, but the *Länder* do not want to spend more money in schools at which the numbers of pupils are decreasing sharply.

There have been protests from the teachers' professional organizations, chiefly the Gewerkschaft Erziehung und Wissenschaft (Union for Education and Sciences) and the Deutscher Philologenverband (German Philologists' Society), but they represent only the employed teachers and there is little solidarity.

The ministers meet regularly, but they usually postpone discussion of this issue to their next meeting. They have not managed to answer even the most pressing question: how can the reduction of working hours — agreed for all civil servants during the union negotiations in 1984 — be applied to teachers? The absurd situation exists where one fewer teaching hour each week for all 590,000 teachers in post would provide jobs for 22,400 of their unemployed colleagues: education experts in both the Social Demorcatic and the Christian Democratic parties recommend such a reduction, but the civil servants have so far been successful in their opposition. They themselves are asking for more jobs to be created before they will agree to any kind of compromise.

The ministers, however, know that something must be done, even at this late stage. In Bavaria, all teachers over the age of 55 are to have their working week reduced by two hours. Nordrhein-Westfalia has given some applicants jobs for three-quarters of the time, but only on a three-year basis. Many unemployed teachers are, however, unwilling to give up jobs as taxi drivers, innkeepers, clerks or sales representatives only to face even bigger problems in three years' time.

At present, almost 5 per cent of West Germany's unemployed are teachers, but the proportion is growing dramatically. The vice-president of Munich University, Otto Speck, predicts an increase of 72,000 in 1986. The schools are facing "Vergreisung" (a growing percentage of older teachers), but the finance ministers of the *Länder* contine to argue that "teachers cannot be a privileged group among the unemployed".

Jürgen Neffe

West German universities

SIR—Your article on West German universities (*Nature* **316**, 96; 1985) only reflects part of the actual situation.

The concept of "shifting balance within the university committees to a wider group" was indeed an integral part of the university reform that was rushed through some *Länder* parliaments in the early 1970s, without consulting academic staff. The anti-industry attitude then prevailing also led to the institutionalization of rigorous limitations on *Drittmittelforschung*, that is, industry-supported research. The idea was to reduce if not abolish access of individual staff members to research funds, and to ensure control of all departmental activities by "democratic" committees that were usually dominated by extreme left-wing activists.

The new legislation required all decisions concerning such divergent matters as professional appointments, finance, extension of contracts of laboratory assistants or undergraduate courses to be arrived at by majority vote in "democratic" committees. The resulting meetings occupied a considerable part of the staff's time — up to 90 hours per month was not unusual. Plans to abolish individual examinations as relics of capitalist exploitation and to accept examination papers produced by teams of comrades, so that the strong could support the weak, have been seriously discussed in this context.

This led to a decrease in research activities and further weakened the potential of German universities which had suffered from the exodus during the early years of Nazism, from twelve years of dictatorial rule and persecution and from the war. It is no accident that research papers from German universities are only rarely found in the pages of *Nature*, while the independent Max-Planck Institutes (MPIs) are now the main source of internationally recognized research in Germany. The same applies to the job situation — openings advertised in *Nature* are usually in MPIs and not in universities.

You refer to professorships that "were distributed too readily during the years of expansion"; the years of expansion were the 1960s, when common sense still prevailed; ready distribution of professorships took place under the new university regulations when pressure from the non-professional majorities on committees resulted, for instance, in the University of Hamburg elevating 400 lecturers to professors (not on merit!) by a single decree.

This is why prospects for promotion in universities are now discouraging and why the scientific standard of professors in "reformed" German universities does not compare favourably with the United Kingdom.

Let me conclude by saying that my friends in British universities are invariably horrified when they learn about the new German "system", which, in recent years, has also been adopted in my native Austria. A head of department is now a mere figurehead who has to maintain the goodwill of the powerful departmental committee by populist measures or by bowing to the majority of the less-qualified. A more appropriate title for your article would thus have been "Is there still hope for German universities?" — by dropping the unrealistic and unproductive "plans for change" before it is too late. Isolation from the international scientific community and lowering of standards in teaching and research would otherwise be inevitable.

Prizes for Germany

SIR—When Klaus von Klitzing said (see *Nature* **317**, 667; 1985) that he hoped it would not be another 22 years before a West German won a Nobel prize (for physics), he was *not* referring to the prize awarded that long ago to the Munich physicist Mössbauer, but to the Heidelberg physicist J. Hans Jensen (1907 – 1973), who shared the Nobel prize for physics in 1963 with Maria Goeppert-Mayer, La Jolla (one half of the prize, the other half was awarded to Eugen Wigner, Princeton). Rudolf Mössbauer, München, shared the Nobel prize for physics 1961 with Robert Hofstadter, Stanford.

ROSWITHA SCHMID

Naturwissenschaftliche Rundschau,
Postfach 40,
D-7000 Stuttgart 1, FRG

UK physics

SIR—I read "Sociological problems of high-energy physics" (*Nature* **318**, 243; 1985) with interest but with some dismay, as I did not entirely recognize the field in which I work from the text. The article indulges happily in unsupported generalizations, and hypotheses based on speculations by the gurus of long ago. Perhaps from their American viewpoint they do not see the vitality and innovation of the field over here. Nobody looking at the L3 and DELPHI experiments at LEP could consider them as conservative. Even a project such as OPAL, founded on the premise that it must work reliably from turn-on, is benefiting every day from the individual initiative and innovation of its younger members.

The "10–25 per cent heterodox research" advocated in the article is thriving in the United Kingdom (see the 1984 Rutherford Annual Report for a full list) but will have to diminish if the cuts recommended in the Kendrew report are inflicted.

There is a sociological problem in high-energy physics, certainly in the United Kingdom, forced on us by the persistent negativism of our paymasters. First-rate researchers leave the field, for lack of career advancement, and young people are discouraged fron entering as the number of posts is whittled down. (The breathing space afforded by the Science and Engineering Council's New Blood schemes is now over.) This is occurring at a time when the country desperately needs scientists who have been trained in making their mark in a European environment. British industry is not going to be helped by seeking artificially sheltered conditions in which to train our best researchers.

It is fashionable to decry high-energy physics now. Let us not be misled. In spite of official discouragement, the field remains a vital and exciting one in which to work.

AFRC cuts

SIR—Over the past few years you have given detailed consideration to the financial problems of the Agricultural and Food Research Council (AFRC), culminating in your report of the severity of the latest cuts at this institute (*Nature* **317**, 663; 1985).

It is not, however, generally appreciated that the extensive cuts at the Institute for Research on Animal Diseases include the savaging of the molecular biology department, which was set up some four years ago to introduce genetic manipulation and allied techniques to the institute's research programme. In view of the stated commitment of AFRC to a programme of modern biology, one would have expected maintenance or even expansion of this programme.

On the contrary, the number of permanent scientific staff in the department has declined at a faster rate than that of the institute staff as a whole. At a time when molecular biology has expanded elsewhere, it is strange that the opposite should be true of AFRC's restructuring plans at this institute.

Growth by cannibalization

A new calculation of the process of condensation suggests that more attention should be paid to the correlations between neighbouring droplets.

HERE is as neat a piece of classical physics as one could hope to find. The problem is the apparently simple one of predicting the behaviour of an assembly of droplets such as might be found in a condensing cloud in the atmosphere. Large drops will grow at the expense of smaller drops. The classical problem, of obvious importance in meteorology, is to know how the size distribution changes with time. It is now thirty years since the essentials of the problem were stated and solved by two Soviet physicists, I.M. Lifshitz and V.V. Slyozov. The nub of their result is that, where large droplets grow at the expense of small, the average radius increases with time (t) in proportion to the cube root, $t^{1/3}$.

This cube-root dependence on time of the average radius of the droplets in a cloud seems to be borne out by observation, not merely of the sizes of droplets in an atmospheric water cloud but in other comparable situations, the radii of particles crystallizing from a molten metal, for example. But the other features of the size distribution predicted by Lifshitz and Slyozov are not nearly as well established. And now Dr M. Marder from the University of California at Santa Barbara has been able to correct the older arguments in a particularly interesting way (*Phys. Rev. Lett.* **55**, 2953; 1985).

Because the vapour pressure of a small droplet varies inversely with its radius, small droplets are unstable, and will evaporate rather than grow unless the vapour pressure in the immediate environment is greater than that corresponding to equilibrium. This is why cloud formation requires some mechanism of nucleation, and why the environment of a cloud usually manifests a degree of supersaturation with respect to the equilibrium vapour pressure of bulk water at the temperature of cloud formation. But if those conditions are met, it also follows that large droplets will grow at the expense of smaller droplets.

The practical need is to derive quantitative estimates of the preferential growth of larger particles. The process is dominated by diffusion; a shrinking small drop will not be able to continue shrinking if evaporated water vapour accumulates near the drop, increasing the local vapour pressure above equilibrium value. Similarly, a large drop will not be able to continue growing if it should so denude the local environment of water that the vapour pressure is less than the equilibrium value. So the rate of growth of a particular droplet may be determined by its immediate past history (which determines whether the immediate neighbourhood is enriched by or depleted of water vapour), as well as by the behaviour of nearby droplets which, by shrinking or growing, may add or subtract water vapour from the environment.

The problem is therefore one in kinetic theory, but with the proviso that equilibrium does not apply. The first successful treatment seems to have been given by the two Soviet physicists. Their argument may be summarized as follows. The simplest case is that in which the medium in which the droplets grow is so massively supersaturated that neighbouring drops have no influence on each other and even the effects of surface tension can be neglected. Then, the rate of growth of a particular drop will be determined by the rate at which water vapour can diffuse to reach its surface. In terms of the radius, R, the rate of change will be the simple function $(D/R).\,Q^\circ$, where D is the molecular diffusion constant, Q° is the mixing ratio of the water vapour expressed as the ratio of the volume of the water if it were totally condensed to that of the total space occupied and R enters the equation reciprocally because of the geometry of diffusion onto a small supposedly spherical droplet through the surrounding medium.

A missing ingredient from this extreme approximation has the effect of subtracting from Q° an amount d/R, where d is some quantity proportional to surface tension and the reciprocal of R, appearing as a factor. This accords physically with the circumstance that the effect of surface tension is to reduce the rate of growth of drops, the smaller the droplet the more markedly.

The other obviously missing ingredient is some allowance for the extent to which one drop influences its neighbours. First, it is necessary to adjust Q° (by subtraction), the volume fraction of the water already condensed, and then to allow for the way in which the growth of a particular droplet is affected by all the behaviour of all the other droplets in the system, by a separate adjustment representing the influence of each of them. Shrinking droplets will add to the availability of material elsewhere, which explains why the rate of change enters linearly in each adjusting term, adding to the availability of material (and thus Q° when it is negative). The radius of every other drop, or rather its square, also enters, but the distant effect of each droplet is attenuated in the same way as diffusive effects are invariably attenuated by gaussian factors in respect of both distance and time; in short, the growth of a particular droplet will be more affected by the recent behaviour of other nearby droplets than by the remote (in time) behaviour of distant droplets. The result is a horrid set of nonlinear interlocking equations that nobody would think of solving directly, not merely because solution would be impossible but because the problem is in any case statistical.

Lifshitz and Slyozov dealt with the problem by averaging, on the specific assumption that drops of different random sizes are randomly distributed through the available space. Apart from their conclusion about the average size r, they also concluded that the size distribution of growing droplets, strictly a function both of radius and of time, should ultimately be given by a calculable function only of the ratio R/r, which of course involves the time as a variable because the average radius r grows with time. Marder's point is that while the cube-root dependence of r has been well confirmed by observation, the size distribution of particles that grow partly by the remote cannibalization of each other usually turns out to be much broader than that calculated.

What can have gone wrong? Marder's answer is simple; Lifshitz and Slyozov had no business to determine the average behaviour of a droplet by assuming that droplets of different sizes may be randomly distributed. On the contrary, Marder says, precisely because a shrinking drop will add preferentially to the growth of its immediate neighbours rather than more distant drops, there will be a tendency for large and small drops to be paired together statistically. By good fortune, the more exact correlation is calculable. The proof of the conclusion is that the calculated size distribution agrees well with data previously gathered for the particle-size distribution in slowly solidifying alloys of Fe-Si-Ti and Ni-Si, both of which are broader than predicted by Lifshitz and Slyozov. More detailed calculations of the evolution of a system of mutually cannibalizing particles can pass through a stage in which there is a distinctly bimodal distribution of size, with one group of smallish particles and another which is much larger.

Sex chromosomes

Mammalian X and Y crossover

from Paul S. Burgoyne

HYPOTHESIS and fact, although semantically distinct, are less easy to separate in the real world. Scientific concepts often seem to weave to and fro across this semantic divide before eventually being universally accepted or rejected. A paper by F. Rouyer *et al.*[1] on page 291 of this issue, together with three others recently published in *Nature*[2–4], present incontrovertible evidence for regular exchange (crossing over) between X and Y chromosomes in both mouse and man. This finally validates the concept of X–Y crossing over which dates back to Darlington in 1934, and must surely persuade even the most persistent doubters[5,6].

In 1982, two papers[7,8] appeared that reiterated the case for genetic homology and crossing over within the X–Y pairing segment in man and other mammals. In my paper[7], I chose to emphasize a conclusion, derived from the unusual inheritance of the sex-reversed factor (*Sxr*) in the mouse, that a single 'obligatory' crossover occurred in the X–Y pairing segment. To describe genes that are exchanged between the X and Y by this crossover and therefore misleadingly seem to be linked to an autosome rather than the X or Y chromosome, I suggested the term 'pseudoasutosomal'. Polani[8] had the foresight to see how molecular genetic approaches could be used to provide the definitive evidence and a search for DNA sequences shared by human X and Y chromosomes ensued. Such sequences were found but, obtusely, they were not located in the X–Y pairing segment. A substantial amount of the X–Y sequence homology proved to be the result of an evolutionarily recent transposition of X-chromosomal material to the Y chromosome[9].

A non-molecular approach provided the first genetic evidence that crossing over is a regular feature of normal X and Y chromosomes: Keitges *et al.*[4] demonstrated that a mouse steroid sulphatase (*STS*) variant, which had seemed to be inherited autosomally, was in fact transmitted to XO offspring via the X chromosome. This observation, together with the existing pedigree data, proved that the mouse *STS* gene was present and expressed on the X and Y chromosomes and that there must be an obligatory crossover proximal to the *STS* locus to account for the absence of either X or Y linkage of *STS*. This pseudautosomal mode of inheritance of the mouse *STS* gene contrasts with that in the human, where the *STS* gene is X-linked, although close to the pseudoautosomal region.

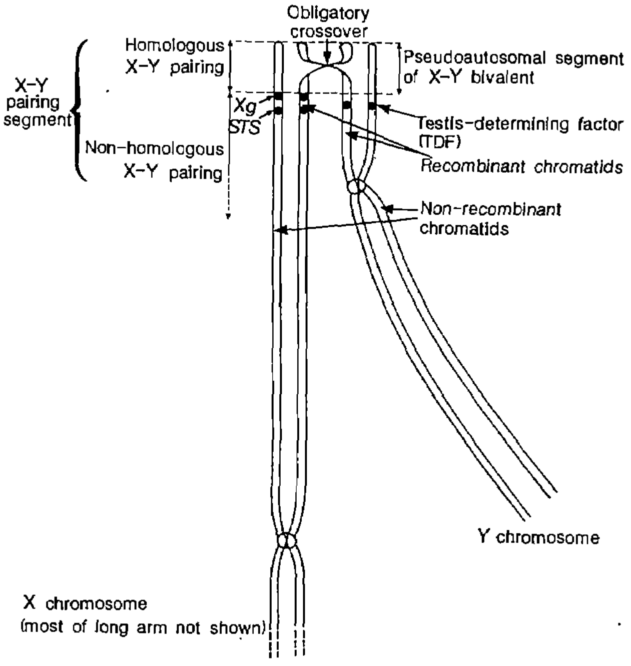
The molecular approach has now also borne fruit with the description of pseudoautosomally inherited human DNA sequences[2,3], culminating in the elegant linkage analysis of three pseudoautosomal loci reported by Rouyer *et al.*[1]. The features of the obligatory X–Y crossover model[7], incorporating the most recent findings, are illustrated for the human X–Y pair in the figure. The existence of an obligatory X–Y crossover, at least in those spermatocytes generating functional sperm, is clearly confirmed by X–Y recombination data[1,4]. This brings the X–Y pair in line with the autosomes, where there is a minimum of one chiasma, the morphological manifestation of crossing over, for each meiotic chromosome pair (bivalent), irrespective of the size of the chromosome.

Although in most mammals no obvious X–Y chiasma can be seen by light microscopy, chiasmate X–Y associations have been demonstrated with the electron microscope[10]. They have not been found in all X–Y bivalents but this could be due to technical difficulties. In some instances the absence of an X–Y chiasma may result from inadequate X–Y pairing. In XY *Sxr* mice there is a high incidence of X–Y separation at pachytene, presumably because the presence of *Sxr* distal to the pairing segment sometimes interferes with the pairing process. Nevertheless, the recombination data for *Sxr* confirm that all functional sperm are derived from spermatocytes that had an X–Y chiasma, adding weight to the view that there is a meiotic 'quality-control' mechanism that prevents primary spermatocytes with unpaired chromosomes from forming viable sperm[11].

I find that it helps to think of the pseudoautosomal segment of the X–Y bivalent as a very small extra pair of autosomes. Rouyer *et al.*[1] estimate that the human pseudoautosomal segment contains 2,000–5,000 kilobases, which would make it about one-tenth the size of the smallest human autosomal bivalent. An obligatory crossover in such a short length inevitably results in a high recombination frequency per unit length[1]. In the X bivalent of females, the obligatory crossover is not constrained within the pseudoautosomal region, so recombination in this region is reduced almost tenfold[1].

What determines the limits of the pseudoautosomal segment? As originally defined[7], it is that part of the X–Y bivalent where there is exchange by crossing over, a definition that includes genes showing partial sex linkage — those with less than 50 but greater than 0 per cent X–Y recombination.

In practice it may be necessary to set an abitrary minimum of say 1 per cent recombinants as defining a pseudoautosomal locus, as it is important to exclude those X-linked (for example, *Xg*) or Y-linked (for example, *TDF*) genes that are occasionally exchanged between the X and Y chromosomes[12] by unknown mechanisms



Obligatory crossover
Homologous X-Y pairing
X-Y pairing segment
Non-homologous X-Y pairing
Pseudoautosomal segment of X-Y bivalent
Xg
STS
Testis-determining factor (TDF)
Recombinant chromatids
Non-recombinant chromatids
Y chromosome
X chromosome (most of long arm not shown)

Crossing over between the human X and Y chromosome. The pseudoautosomal segment is that part of the X–Y bivalent where there can be X–Y exchange by crossing over. X–Y homology in this segment is maintained by, and may be necessary for, this crossing over. There is always one 'obligatory' X–Y crossover but, because its position varies, only the more distal pseudoautosomal loci show 50% X–Y recombination. More proximal loci show a hierarchy of partial sex linkage (<50% but >0% X–Y recombination), reflecting their order within the pseudoautosomal segment[1]. X-dosage compensation is unnecessary for pseudoautosomal genes and they are expressed in double dose in both males and females. X-linked genes bordering the pseudoautosomal segment (*Xg*, *STS*) are also at least partially expressed on the 'inactive' X of females. The length of the X–Y pairing segment varies with meiotic stage and can extend well beyond the pseudoautosomal segment into the Y long arm. Much (perhaps all) of the synaptonemal complex formed outside the pseudoautosomal segment represents non-homologous pairing. (Modified from ref. 7.)

that are not formally distinguishable from crossing over.

These problems of definition apart, what is it that constrains the obligatory crossover to occur in the pseudoautosomal segment of the X–Y bivalent? The constraint is certainly not the length of the pairing segment — in man, X–Y pairing, as defined by the formation of a synaptonemal complex, includes most of the Y short arm and can extend into the long arm, much longer than the pseudoautosomal segment. More probably it is the extent of X–Y homology in the pairing segment.

In other situations where stretches of synaptonemal complex are formed between non-homologous chromosome segments, crossing over is excluded from these non-homologous regions. Because there are degrees of homology, the pseudoautosomal segment may end in a zone where the likelihood of a crossover rapidly decreases in conjunction with a decrease in homology, rather than having a discrete boundary.

It is generally agreed that the heteromorphic mammalian X–Y pair must have evolved from a pair of homologous chromosomes. The pseudoautosomal segment might therefore represent a region of the original homologous pair that has been retained to ensure chiasma formation and orderly X–Y separation at meiotic metaphase I. Although gene-dosage considerations do not preclude the pseudoautosomal segment from exchanging material with the autosomes[7], it may nonetheless be a conserved linkage group with significant homology between mammalian species. If so, with relaxed hybridization conditions it should be possible to use human pseudoautosomal DNA probes to pull out related pseudoautososmal sequences from the mouse genome.

Combining the flexibility of mouse breeding with the exceptionally high recombination frequency in the pseudoautosomal segment should allow a rapid and detailed genetic analysis of this region. Now the molecular geneticists have stuck in their thumbs, I am sure that they will pull out some plums. 1986 promises to be a good year. □

Nuclear winter

Towards a scientific exercise

from K.A. Emanuel

THE detonation of the first atomic bomb on 16 July 1945 changed the world in many ways, not least of which is the view some scientists have taken towards their profession. Many have come to feel that resposibility for the influence of their achievements rests partially with them and should not reside solely with politicians. While imparting certain benefits to political decision making, this attitude has at times tainted the objectivity that is crucial to scientific endeavour. Nowhere is this more apparent than in the recent literature on 'nuclear winter' research, which has become notorious for its lack of scientific integrity. Among the most serious criticisms levelled at this work has been the failure to quantify the large uncertainties associated with estimates of the war-initiated fires and their combustion products, the highly approximate nature of the global circulation models used in the calculations, and the appearance of the results in popular literature before being exposed to the rigours of peer review.

Although controversy continues to surround this work, serious research is beginning to qualify the earlier bold assertions. A good example appears on page 301 of this issue in the paper by B.W. Golding, O. Goldsmith, N.A. Machin and A. Slingo, which attempts to examine the physical factors affecting the disposition of a smoke plume shortly after its inception. These authors point out that previous estimates of the nuclear winter effect have relied either on one-dimensional models, which must assume a uniform distribution of smoke, or on three-dimensional models with grid intervals too large to resolve mesoscale (medium-scale) circulations very near recently initiated plumes. Yet it is likely that such circulations would result from the horizontal temperature gradients produced by radiative heating of the smoke.

Using a mesoscale numerical model, Golding *et al.* show that mesoscale ascent rates of 20 cm s^{-} are possible 12 h after plume initiation; such rates will rapidly lead to condensation of water vapour even in circumstances where the air is initially quite dry. Subsequent scavenging of the smoke by precipitation could substantially alter the characteristics of the plume before it diffuses into the continental-scale pall which is the starting point of most nuclear winter calculations.

The calculations presented by Golding *et al.* are themselves dependent on assumptions concerning the concentration, geometry and radiative characteristics of the smoke plume and the large-scale meteorological conditions in which it is released, and the model does not explicitly deal with the interaction of condensed water and snoke particles. The results do strongly suggest, however, that more attention must be paid to the mesoscale characteristics of the plume in the first day or so of its lifetime. The paper is a welcome step in transforming nuclear winter research from a means of political advocacy to a scientific exercise. □

Archaeology

Reconstructing ancient diets

from Richard Burleigh

A PAPER published recently (*Nature* **317**, 806; 1985) and one on page 321 of this issue make significant new contributions to the investigation of ancient human diets by the analysis of stable isotopes in skeletal remains. In the first, M.J. DeNiro is concerned with the detection of changes in the composition of sub-fossil bone (diagenesis) that might lead to false results. The other, by S.H. Ambrose and M.J. DeNiro, deals with reconstruction of patterns of diet in humans who are known from historic records or presumed from archaeological evidence to have followed particular modes of subsistence. Both papers help to provide a firmer basis for possible investigation of human diet in the much more remote past.

Measurement of the ratios of stable carbon isotopes ($^{13}C/^{12}C$) in collagen from skeletal remains has been used successfully in recent years to establish prehistoric human diets and hence, somewhat more inferentially, patterns of subsistence in the past, for example, in parts of North America, Africa and north-west Europe. The basis of this method is that the carbon-isotope composition of collagen in bone reflects the isotopic composition of the plants that form the base of the food web, isotope ratios being expressed as $\delta^{13}C$ values, or the difference in parts per thousand from a standard, as measured by mass spectrometry. Thus, the relative importance in the diet of C_3 and C_4 plants, which have different photosynthetic pathways characterized by distinct $\delta^{13}C$ values, can be determined. Marine sources of food can confuse this picture but more recently it has been found that, by simultaneous measurement of stable nitrogen ratios ($^{15}N/^{14}N$), the respective contribution of marine and terrestrial sources of food can be distinguished from the differences in $\delta^{15}N$. Because there is a small incremental enrichment of ^{13}C and ^{15}N as these isotopes are moved up the food chain, the $\delta^{15}N$ values in particular also give an indication of the relative importance in the diet of animal products compared with more direct exploitation of plant foods.

Ambrose and DeNiro have investigated the $\delta^{13}C$ and $\delta^{15}N$ values of collagen recovered from the bones of about 100 individuals representative of particular groups of hunter–gatherers, pastoralists and agriculturalists both from the historic period and from archaeological sites in Kenya, Tanzania and South Africa. The bones of wild mammalian species representing browsers feeding mainly on C_3 trees, of grazers feeding mainly on C_4 grasses and of carnivores, also analysed, showed isotopic differences clearly reflecting these animals' diets (with an apparent preference by carnivores for preying on grazers). These results provide a convincing demonstration that in the same biome in Africa, human diets based variously on C_3 and C_4 plants, meat of grazing and browsing animals, and other animal products such as milk and blood, should be distinguishable by a combination of the $\delta^{13}C$ and $\delta^{15}N$ values.

The diets of the historic populations investigated were known from ethnographic records, and Ambrose and DeNiro found very close agreement of the isotope values with this evidence. This in turn gives confidence that their reconstruction of the diets of the prehistoric groups from isotope analyses is essentially correct, as direct archaeological evidence of food resources in the form of animal and plant remains is inevitably incomplete and may sometimes be misleading.

A logical step from this is, the authors suggest, the intriguing possibility of reconstructing the diets of much earlier human ancestors. The living primates most closely related to *Homo sapiens* are predominately C_3 plant feeders. Australopithecines probably were as well, but there is evidence to suggest that the true hominids, *H. habilis* and *H. erectus*, were more dependent on meat. Independent validation of this could have great importance for the study of human evolution, but depends entirely on the isotope record being preserved in bones of Pliocene–Pleistocene age, that is, at least 4 million years old. This may be unattainable in practice, though the photosynthetic pathways with their isotopic differences were certainly established well before then.

A more immediate question is raised by DeNiro, who examines the assumption, implicit in most previous studies, that the isotopic composition of collagen in the bones has not subsequently been adversely altered. Inevitably sub-fossil bone will have undergone physical and chemical changes, which may have resulted in the addition or removal of organic components; much therefore depends on the extent to which the organic fraction used for analysis represents the original collagen. To test this, he analysed bones of marine carnivores and terrestrial herbivores from archaeological sites varying in age from hundreds to thousands of years, and from various depositional environments ranging from arid desert conditions to peat bogs. These species were chosen because the feeding patterns and isotope values of their modern counterparts have previously been well established.

DeNiro finds that, independent of age, those sub-fossil bones with C/N ratios in the range 2.9 to 3.6, characteristic of fresh modern bone, have $\delta^{13}C$ and $\delta^{15}N$ values consistent with expectation. In contrast, burnt bones, where the C/N ratios are outside the normal range, have isotope values that are shifted erratically. It is a reasonable assumption that at least some of the other, often individually indeterminate, diagenetic processes to which sub-fossil bone is subjected might produce similar isotopic shifts. A sensitive criterion, representing the sum of these processes, that allows altered material to be easily recognized and rejected in advance is therefore of the greatest value, although it cannot be applied retrospectively to previous studies without published C/N ratios.

The determination of stable carbon and nitrogen isotope ratios also has purely biological applications, for example, to the investigation of the differential feeding patterns of closely related animal species living in restricted environments, such as those found on remote oceanic islands. These two new papers not only add rigour to a scientific method that is beginning to give results of real importance to archaeologists and anthropologists but are also highly relevant to the refinement of other applications of the method. □

Ecology

Tundra river transformation

from S.I. Heaney

THE past quarter century has seen a great interest and concern over anthropogenic phosphorus loading of lakes and reservoirs. Such enrichments of standing waters often lead to the formation of troublesome surface blooms of algae and deoxygenation of the colder lower layers (Edmondson, W.T. & Lehman, J.T. *Limnol. Oceanogr.* **26**, 1; 1981). Much less attention has been paid to the role of phosphorus in running waters. So the report by B.J. Peterson *et al.* (*Science* **229**, 1383; 1985) on the effects of experimental addition of phosphorus to a nutrient-impoverished arctic river is both important and surprisingly overdue.

Peterson's group added phosphorus to a portion of the Kuparuk River in the Alaskan tundra, raising the concentration of PO_4-P from ambient levels of $< 1-4\ \mu g\ l^{-1}$ to $10\ \mu g\ l^{-1}$, and then monitored the river upstream and downstream of the site of addition. Within six weeks the biomass of the algae (measured as µg chlorophyll *a* per cm^2) attached to the stones on the river bottom had increased tenfold within a kilometre of the site of phosphorus addition. This increased biomass was sustained for several kilometres downstream but there was a negligible change of biomass upstream. The result is probably to have been expected considering the concentrations of other dissolved plant nutrients (carbon, nitrogen) in the stream water. However, the strength and originality of the work lies just as much in the efforts made to separate and quantify the microbial metabolism into heterotrophic (bacterial) and autotrophic (algal) processes and to attempt to see how these induced microbial changes influenced the higher tropic levels (dominant aquatic insects) of the ecosystem.

No less than eleven authors from four institutions were involved in the study, which involved several disciplines and techniques and made possible a holistic approach to this relatively simple ecosystem. Although the results are necessarily restricted they appear convincing enough to support the conclusions: first, photosynthesis and biomass production in the river are limited by phosphorus concentration. Second, on the addition of phosphorus, photosynthetically fixed energy replaced organic matter entering the stream as the major energy source. Third, as a result of increased photosynthesis, algal activity increased on rocks of the river bottom. And fourth, as illustrated by the increase in the size and developmental stage of some aquatic insects, there was food limitation at higher trophic levels in this nutrient-poor environment.

This innovative experiment provokes further questions. Phosphorus was added only during July and August when water temperatures were between 7 and 14°C. As some freshwater algae, including diatoms, can grow at temperatures down to freezing with enough light and nutrients, what would be the effect on the community if phosphorus were added throughout the ice-free period? With continuously elevated phosphorus concentrations, what would be the long-term consequences on the abundance and periodicity of algae other than diatoms? Is the timing of the spring algal growth period significant in relation to the emergence and growth of dominant insect grazers? What is the relationship between suspended phytoplankton and attached algae?

Answers to some of these questions can be sought from studies of phosphorus-enriched rivers. Nevertheless, the experimental work of Peterson's group, earlier pioneer work in experimentally increasing heterotrophic microbial production in trout streams in Oregon (Warren C.E., Wales, J.H., Davis, G.E. & Doudoroff, P. *J. wildl. Mgmt.* **28**, 617; 1964) and that of the Freshwater Biological Association using its experimental circulating channels (Marker, A.F.H. & Casey, H. *Phil. Trans. R. Soc.* **B298**, 265; 1982) will be vital for a fuller understanding of the processes controlling production in rivers. ☐

Developmental biology

Unscrambling egg structure

from Hugh Woodland and Elizabeth Jones

In these columns, we recently reviewed the evidence for the suggestion that the complexity of the amphibian embryo is generated by progressively more complex interactions between a few cell types in the early embryo[1]. These cell types, possibly just the ectoderm and endoderm, probably arise by the partitioning of different cytoplasmic constituents from the egg. What could these differences be?

In the amphibian, one of the few ways to identify them is to pick a molecule and look for its uneven distribution in the egg. There is some evidence from other organisms, particularly insects, that RNA which specifies future cell types is distributed in this way. Several groups have now looked to see if particular messenger RNAs show differences along the animal–vegetal axis of *Xenopus* eggs. *In vitro* translation has shown that at least 17 mRNA species are asymmetrically distributed, which is 4 per cent of the total translatable RNA[2].

The logical extension of this approach is to clone such mRNAs; this has now been achieved for four mRNAs which are concentrated in either the animal hemisphere (An1–3) or in the vegetal hemisphere (Veg1)[3]. All these RNAs are accumulated steadily during oogenesis and two of them, An1 and Veg1, are synthesized only during oogenesis and disappear during gastrulation. The behaviour of these transcripts, especially An1 and Veg1, suggests that they have an interesting role in development.

The ease with which antibodies, as well as sense and anti-sense RNA, can be injected into specific cells in the cleaving embryo suggests obvious approaches to finding their function. Sequencing the clones also suggests a function for the mRNAs; it would be particularly interesting to find hints of activities that could set up positional information (such as gradients of small molecules) to provide the spatial coordinates by which developing cells sense their position and respond accordingly.

Drosophila

If one employs genetics to approach this same subject, one can at least start with a knowledge of what the genes do in the developing animal, because they will have been identified by virtue of some interesting, probably dramatic, effect on the developing embryo. This is why current intense activity in *Drosophila* developmental genetics is so exciting for embryologists of all kinds. Most such work recently published in these pages has been concerned with homoeotic genes, like those of the antennapedia complex, or the segmentation genes, for example, *fushi tarazu* and *engrailed*. These genes are expressed after fertilization and interpret spatial cues established at earlier stages. The latter are produced by other genes transcribed during oogenesis, that is, they are 'maternal effect' genes. These genes do not affect the maternal carrier, but their malfunctions are revealed as abnormalities in all eggs produced by females carrying any copies of the mutant gene in the case of dominant genes, or lacking wild-type genes in recessives. Such genes have global effects on the major body axes of the embryo, to be expected if they set up some kind of network of positional information, such as gradients.

Judging by the major classes of maternal mutants discovered, there seems to be two kinds of positional information in the early insect embryo, that for the antero-posterior axis and that for the dorso-ventral axis. These two sets of information would be sufficient to make every point in the left or right halves of the embryo unique. Our knowledge of the dorsal group of genes has mainly derived from the work in Christiane Nüsslein-Volhard's laboratory[4-6]. At least 10 separate loci are involved in establishing the dorso-ventral axis, all manifesting themselves as recessive mutations in which the developing embryo lacks cells of the ventral type. Because a recessive mutation usually results in the loss of function of a gene (for example, its deletion, or encoding of a non-functional protein) this indicates that the products of these genes are necessary to form ventral structures (their confusing name of 'dorsal-type' is because genes are typically named after the observed effect of their malfunction, and not that of their normal function). A particularly important feature of most of these genes is that they can be rescued by injecting cytoplasm into the eggs of mutant females, thus restoring the normal phenotype at least to some extent. In all cases where this can be achieved except one (*dorsal*), pure RNA is also effective (see table).

Two recent reports[7,8] indicate that one of these maternal effect genes, *Toll*, is particularly interesting. *Toll* is unique among such genes because it not only has recesive, lack-of-function dorsalizing alleles, but also has dominant gain-of-function ventralizing alleles. Perhaps the most immediately striking observation about all the dorsal-type mutants is that among the mutants rescuable by injection with RNA, it is only in *Toll*$^-$ embryos (those laid by females homozygous for *Toll*$^-$ recessive mutations) that it matters where the cytoplasm or RNA is injected[4]. The point of injection marks the future ventral region of the rescued embryo. In the other dorsal-type mutants, the ventral region is always in the usual place, recognizable by the asymmetrical shape of the egg. This indicates that the dorso-ventral polarity still exists in some form in these embryos,

Maternal effect loci affecting the dorso-ventral axis (from refs. 6 and 7).

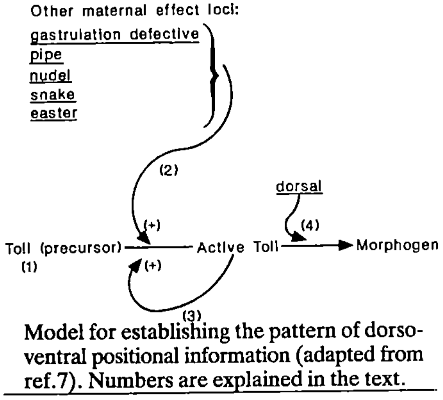
but needs the expression of the non-*Toll* dorsal-group genes to be interpreted. *Toll*$^-$ embryos must have no inherent dorso-ventral axis, and at least a partial axis is organized at the position where normal cytoplasm is injected.

Anderson, Jürgens and Nüsslein Volhard have conducted an intensive genetic analysis of *Toll*, which has led them to postulate that the *Toll*$^+$ product is immediately involved in setting up the hypothetical morphogen gradient that establishes the dorso-ventral axis[7]. It cannot be the morphogen itself because rescue of the eggs of *Toll*$^-$ females can be achieved with cytoplasm taken from anywhere in the wild-type egg (see figure).

Although the *Toll*$^+$ product is evenly distributed throughout the embryo, it is presumably only active in the ventral region. Hence it may be present as a precursor which is activated only in this region (1 in the figure). The 'precursor' could be mRNA, in which case 'activation' is its controlled translation. Because *Toll*$^+$ RNA produces a ventral region where it is injected into an egg lacking the *Toll*$^+$ product, they propose that the precursor self-activates in the absence of other *Toll*$^+$ products, although this explanation is not very satisfactory without further evidence.



Model for establishing the pattern of dorso-ventral positional information (adapted from ref.7). Numbers are explained in the text.

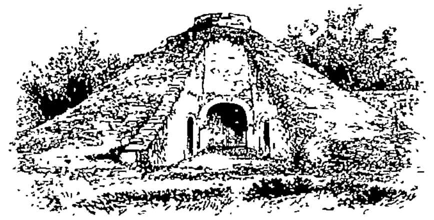
There are four dominant alleles of *Toll*, divided into two groups. In eggs from heterozygous females carrying all these mutations, only ventral structures are present. When one of the pair of alleles *Tl*^{5B} and *Tl*^{84C} is present together with any homozygous dorsal-type recessive mutation from those listed in Table 1, the resulting embryos have only dorsal structures. Thus, *Toll* requires each one of these dorsal-type gene products for its activity (2 in the figure). Furthermore, these dominant alleles *Tl*^{5B}and *Tl*^{84C} only produce their totally ventral phenotype when there is also a copy of *Toll*$^+$ present, that is, in the absence of normal *Toll*$^+$ product they produce the totally dorsalized phenotype characteristic of no *Toll* activity, as seen in the recessive *Toll* mutants. This could mean that *Toll* produces a multisubunit protein, which needs some normal subunits for these dominant alleles to exert their effect. However, the authors favour the possibility that the active form of the product stimulates its own synthesis, *Tl*^{5B} and *Tl*^{84C} having lost this function.

The other two dominant alleles of *Toll* (*Tl*^{I} and *Tl*^{9Q}) will at least partially override all of the dorsal-type genes, except *dorsal* itself, to produce intermediate lateralized embryos. In addition, these alleles do not need the presence of a normal *Toll* gene for their expression. It is therefore assumed that *Tl*^{I} and *Tl*^{9Q} bypass the precursor activation step by making an altered *Toll* product that is active or self-activating, hence uncoupling the dependence of *Toll* on the other dorsal-type genes and eliminating the positive-feedback loop (3 in the figure). The role of the dominant alleles of *Toll* in interactions with other dorsal-type genes has also been investigated by cytoplasmic rescue experiments[8]. The cases of *gastrulation defective* and *pipe* are especially interesting, because eggs affected by mutations in these genes cannot be rescued by the injection of normal cytoplasm. This can perhaps be explained for *gastrulation defective* as it has a temperature-sensitive period (time of activity) from before to a little after fertilization, earlier than the other genes tested. Thus, cytoplasm is injected into these eggs too late to effect rescue. However, cytoplasm from the *Tl*^{9Q} dominant eggs will rescue them, emphasizing the escape of the *Tl*^{9Q} product from control by the other genes.

All the *Toll* dominant alleles require the presence of an active *dorsal* gene in the female to produce their ventralizing effect (4 in the figure). This suggests a special position for the *dorsal*$^+$ product. It is put later in the chain of events because rescue by *dorsal*$^+$ cytoplasm requires the injection to be ventral, that is, into the area where the hypothetical *Toll* product is activated. *Dorsal*$^+$ has an early time of action, overlapping but extending longer than *gastrulation defective*. It can only be rescued by cytoplasm and not by RNA, suggesting that it is translated early on. However, it is a puzzle that the *dorsal* RNA is actually present throughout early development[10]. Validation of this interesting model will require the cloning of the genes concerned, which is no small task.

It is intriguing that a new example of a maternal effect gene has been isolated by virtue of its containing a homoeo box sequence[11]. This gene, *caudal*, is unknown genetically but is expressed in oogenesis and its product becomes localized to a band at the posterior tip of the embryo at the cellular blastoderm stage. This gene may be a relative of the bithorax complex controlling the development of the partially suppressed ninth abdominal segment. The most interesting feature of *caudal* is that it is the first maternally expressed *Drosophila* gene with a homoeo box, although one such *Xenopus* gene also has this sequence[12]. This suggests a new way to obtain genes that control patterns of vertebrate development, and re-emphasizes the considerable general impact of *Drosophila* genetics.

100 years ago



THE Lions' House in the grounds of John Hunter's house at Earl's Court. It was "a raised mound of earth. The earth rests upon an arched structure, which, at the time of my visit, was in excellent condition." The sketch was one of a series of homes and birthplaces of illustrious men drawn by Bertram Richardson.
from *Nature* **33** 275, 21 January 1886.

Finally, there are two parallels which may be drawn between the establishment of the dorso-ventral axis in insects and vertebrates. First, the key area in the dorso-ventral positional field of insects is the ventral part of the embryo. This is where the mesoderm develops, and the region is supposed to organize the dorso-ventrally graded ectoderm dorsal to it by some kind of long-range interaction. In vertebrates, the central nervous system (the most dorsal ectoderm) is also generated by a signal from the mesoderm, the phenomenon called neural induction[1]. Second, in insects the ventral *Toll*$^+$ component may be generated by activation of an inactive precursor (or translation of an RNA). It is proposed that the amphibian dorso-ventral axis is also generated by the unmasking of a ubiquitous component, although here it marks the dorsal limit of the dorso-ventral axis and the response is polarized by a cytoplasmic movement, usually in response to sperm entry[13]. The parallels are certainly intriguing and it will be fascinating to see how real they are. ☐

Solar physics

What causes the solar cycle?

from Douglas Gough

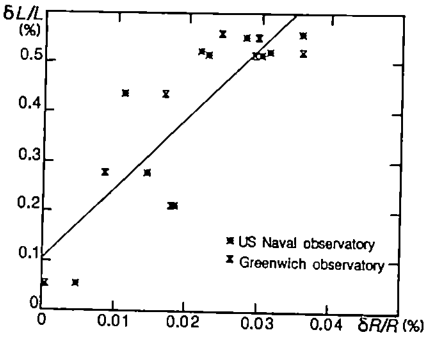
THE dynamics of the solar cycle are not understood. The main obstacle to progress is the paucity of data in a form that is immediately pertinent to the alternative theories that have been put forward to account for the cycle. That situation is bound to be improved by the interesting new analysis of solar magnetic fields reported by J. O. Stenflo and M. Vogel on page 285 of this issue[1].

The most popular theories presume that the cycle results either from a coherent magnetically controlled global oscillation of the Sun, or from some dynamo process that is essentially confined to the turbulent convection zone and possibly its immediate environs. The first alternative is perhaps the more obviously appealing, for it yields the observed 22-year period in a quite natural way, requiring simply that there is a large-scale internal magnetic field whose intensity is comparable to that observed in sunspots. Dynamo theories are less transparent, but they can rationalize the observed period by adjusting the quite uncertain statistical properties of the turbulence. They have been more highly developed, and consequently have gathered a larger following. But their failure to explain, in particular, the migration towards the equator of the sunspot belts has cast doubts even in the minds of some of their most ardent supporters. There is also evidence that the mechanism of the cycle extends well beneath the base of the convection zone.

One of the first hints that the solar cycle is not confined to the convection zone came from a dendrochronological analysis by Stockton *et al.*[2] of drought in North America. It was anticipated there would be a correlation with the solar cycle, with a period of 11 years. If contemporary dynamo models were correct, the entire magnetic field would be the same every half-cycle. Because the structure of the Sun cannot depend on the polarity of the field, any solar variation that might influence the climate should therefore have the 11-year period.

But to everyone's surprise, the drought period was found to be 22 years. Therefore the Sun can sense the difference between its north and its south, which can be so only if there is a nonreversing field, presumably in the radiative interior, that is strongly coupled to the oscillating field outside. It has been claimed that the Princeton oblateness measurements[3] and the fine structure in the power spectrum of low-degree acoustic oscillations[4] also show indirect evidence for a deep-seated magnetic field. Moreover, the existence of widely spaced stable longitudes of magnetic activity seems to be more readily comprehensible if there is a coherent field that extends into the radiative interior.

The climatic record could be regarded as no more than a clue, for perhaps the solar–terrestrial connection filtered the 22-year period: if climatic variation results from the modulation of the Earth's ionosphere by charged particles from the Sun, it could be that the geomagnetic field determines the invariant direction. However, corroborating evidence that the direction is determined in the Sun was provided by Sonnet[5], who pointed out a systematic difference between odd and even sunspot cycles. And more recently, Eddy and Fröhlich[6] have found decade timescale variations in 17-year records of solar constant and diameter measurements that seem to be consistent with a 22- but not a 11-year periodicity.



Relation between relative radius ($\delta R/R$) and solar luminosity ($\delta L/L$) variations in the period 1967–1982 (after ref. 6).

Another interesting result that emerged from the analysis by Eddy and Fröhlich is the ratio, W, of the infrared relative radius and solar luminosity variations (see figure). It had previously been shown that the value of W is an indicator of the depth, d, in the Sun at which the variations are produced[7] and it had also been conjectured that W is an increasing function of d. Eddy and Fröhlich obtained a value for W ($\simeq 0.078 \pm 0.026$) which points to a disturbance near the base of the Sun's convection zone, a natural location for the alternating external field and the direct internal field to meet, rather than in the superficial layers or the energy-generating core. One is reminded of the proposal by Spiegel and Weiss[8] that the main role of the turbulence in the convection zone is to concentrate the field at its base until instability causes the field to erupt into the start of a new sunspot cycle.

This argument too must be viewed with caution. Variations in the Sun's diameter are notoriously difficult to measure. On timescales of centuries widely divergent results have been reported. Much of the discrepancy has been attributed to errors introduced by changes in the observing conditions. The data analysed by Eddy and Fröhlich[9] seem to have been obtained under relatively uniform conditions, so perhaps their variation is a more reliable indicator of a corresponding solar variation. But, they may not reflect gross compressions and rarefactions of the Sun; superficial changes in the scale of solar granulation and in the structure of the solar atmosphere that have been reported to be correlated with the 11-year sunspot cycle may have 22-year counterparts that influence the size of the solar image.
